The **uterine plexus** arises from the caudal portion of the pelvic plexus. It approaches the uterus from its caudal and lateral aspect in the base of the broad ligament, in the same region as the uterine artery. It is distributed to its musculature, supplies filaments to the uterine tube, and communicates with the ovarian plexus (Curtis et al., 1942).

## Organs of the Special Senses

Endings of the sensory nerves of the peripheral nervous system are found in end organs which may be divided into two large groups: (1) the organs of the special senses of smell, taste, sight, and hearing, and (2) the sensory endings of general sensation of heat, cold, touch, pain, pressure, etc. This chapter considers only the organs of the special senses.

### Organ of Smell

The sensory endings for the sense of smell are located in the nose, and for this reason the entire nose has, by long tradition, been described in this chapter. In this edition, however, all but the olfactory area are described in Chapter 15, the Respiratory System, because the nose and nasal cavity are more important for the passage of air than

for the sense of smell and they are customarily referred to by clinicians as the upper respiratory tract.

The **olfactory region** is located in the most superior part of both nasal fossae and occupies the mucous membrane covering the superior nasal concha and the septum opposite (Fig. 13-1). Thus it is confined to an area of the fossa whose walls are formed by the ethmoid bone.

The olfactory sensory endings are the least specialized of the special senses. They are modified epithelial cells liberally scattered within the columnar epithelium of the mucous membrane. The sensory cells are known as **olfactory cells** and the other epithelial cells, as **supporting cells**. Although the epithelium appears pseudostratified, the supporting cells are not ciliated and there are no goblet cells (Fig. 13-2).

The **olfactory cells** are bipolar, with a small amount of cytoplasm surrounding a large spherical nucleus. The slender peripheral or superficial process extends to the surface of the epithelial membrane and sends out a tuft of fine processes known as **olfactory hairs**. The central or deep process penetrates the basement membrane and in the underlying connective tissue joins neighboring processes to form the bundles of unmyelinated fibers of the **olfactory nerves** (Fig. 13-3). Mingled with the nerve bundles in the subepithelial tissue are numerous branched tubular glands of a serous secreting type (glands of Bowman<sup>1</sup>), which keep the membrane protected with moisture.

The bundles of nerve fibers form a plexus in the submucosa and finally collect into about 20 nerves that pass through the openings in the cribriform plate of the ethmoid bone as the **fila olfactoria**. The nerve fibers end by forming synapses with processes of the mitral cells in the glomeruli of the olfactory bulb (Fig. 13-3; also see page 1050).

### Organ of Taste

The peripheral taste organs (**gustatory organs**) are the **taste buds** (**gustatory caliculi**) distributed over the tongue and occasionally on adjacent parts. They are spherical or ovoid nests of cells embedded in the strati-

<sup>1</sup>Sir William Bowman (1816-1892): An English anatomist, ophthalmologist, and physiologist (London).

**FIG. 13-1.** The nerves of the right side of the septum of the nose.

fied squamous epithelium (Fig. 13-4), and are present in large numbers on the sides of the vallate papillae and to a lesser extent on the opposed walls of the fossae around them (Fig. 13-5). They are also found over the sides and back of the tongue, especially on the fungiform papillae (Fig. 16-36). They are plentiful over the lingual fimbria and are occasionally present on the oral surface of the soft palate and on the posterior surface of the epiglottis.

Each **taste bud** occupies an ovoid pocket that extends through the thickness of the

epithelium. It has two openings—one at the surface and the other at the basement membrane. There are two types of cells within the bud: **gustatory cells** and **supporting cells** (Fig. 13-4). The supporting cells are elongated and extend between the basement membrane and the surface; they form an outer shell for the taste bud, arranged like the staves of a wooden cask. Supporting cells are also scattered through the bud between the gustatory cells. The gustatory cells occupy the interior portion of the bud; they are spindle-shaped and have a large round

**FIG. 13-2.** Section of the olfactory mucous membrane (Cadiat).

FIG. 13-3. Plan of olfactory neurons.

central nucleus. At the peripheral end of each gustatory cell protrudes a delicate hair-like process, the **gustatory hair**, through an opening at the surface, the **gustatory pore**. The central end of the gustatory cell does not end in an axon, as in the case of the olfactory cell, but remains within the taste bud, where it is in intimate contact with many fine terminations of nerves that pass into the taste bud through an opening in the basement membrane. The nerves are myelinated until they reach the taste buds but lose their sheaths as they enter the bud.

**NERVES.** The posterior third of the tongue, including the taste buds on the vallate papillae, is supplied by the glossopharyngeal nerve. The fibers for

FIG. 13-4. Section through a taste bud. Semidiagrammatic 450 X.

taste to the anterior two-thirds leave the brain in the nervus intermedius, continue in the chorda tympani, and reach the tongue in the branches of the lingual nerve. It is believed that taste buds on the epiglottis are supplied by the vagus nerve.

## Organ of Sight: The Eye

The **bulb of the eye**, or **organ of sight**, is contained in a bony cavity, the orbit, which is composed of parts of the frontal, maxillary, zygomatic, sphenoid, ethmoid, lacrimal, and palatine bones. The bulb is embedded in the orbital fat but separated from it by a thin membranous sac, the fascia bulbi.

FIG. 13-5. Section of posterior part of dorsum of tongue showing circumvallate papillae and lingual tonsil. (Redrawn from Braus.)

Associated with it are certain accessory structures—the muscles, fasciae, eyebrows, eyelids, conjunctiva, and lacrimal apparatus.

## DEVELOPMENT

The retina and optic nerve develop from the forebrain, the lens, from the overlying ectoderm, and the accessory structures, from the mesenchyme. The eyes begin to develop as a pair of diverticula from the lateral aspects of the forebrain. These diverticula make their appearance before the closure of the anterior end of the neural tube; after closure of the tube they are known as the **optic vesicles**. They project toward the sides of the head, and the peripheral part of each vesicle expands to form a hollow bulb, while the proximal part remains narrow and constitutes the **optic stalk**. When the peripheral part of the optic vesicle comes in contact with the overlying ectoderm, the latter thickens, invaginates, becomes severed from the ectoderm, and forms the **lens vesicle**. At the same time the optic vesicle partially encircles the lens vesicle, forming the **optic cup**. Its two layers are continuous with each other at the cup margin, which ultimately overlaps the front of the lens except for the future aperture of the pupil (Figs. 13-6 to 13-9). The process of invagination also causes an infolding of the posterior surface of the vesicle and the optic stalk, producing the **choroidal fissure** (Fig. 13-10). Mesenchyme and the retinal blood vessels (hyaloid artery) grow into the fissure. The fissure closes during the seventh week and the two-layered optic cup and optic stalk become complete. Sometimes the choroidal fissure persists, and when this occurs the choroid and iris in the region of the fissure remain undeveloped, giving rise to the condition known as **coloboma** of the choroid or iris.

**RETINA.** The retina is developed from the optic cup. The outer stratum of the cup persists as a single layer of cells which assume a columnar shape, acquire pigment, and form the pigmented layer of the retina; the pigment first appears in the cells near the edge of the cup. The cells of the inner stratum proliferate and form a layer of considerable thickness from which the nervous elements and the sustentacular fibers of the retina are developed. In the portion of the cup that overlaps the lens, the inner stratum is not differentiated into nervous elements, but

forms a layer of columnar cells that is applied to the pigmented layer; these two strata form the **pars ciliaris** and **pars iridica retinae**.

The cells of the inner or retinal layer of the optic cup become differentiated into spongioblasts and germinal cells, and the latter by their subdivisions give rise to neuroblasts. From the spongioblasts are formed the sustentacular fibers of Müller,<sup>1</sup> the outer and inner limiting membranes, and the groundwork of the molecular layers of the retina. The neuroblasts form the ganglionic and nuclear layers. The layer of rods and cones first develops in the central part of the optic cup and from there gradually extends toward the cup margin. All the layers of the retina are completed by the eighth month of fetal life.

**OPTIC NERVE.** The optic stalk is converted into the optic nerve by the obliteration of its cavity and the growth of nerve fibers into it. Most of these fibers are centripetal and grow backward into the optic stalk from the nerve cells of the retina, but a few extend in the opposite direction and are derived from nerve cells in the brain. The fibers of the optic nerve receive their myelin sheaths about the tenth week after birth. The **optic chiasma** is formed by the meeting and partial decussation of the fibers of the two optic nerves. Behind the chiasma, the fibers grow

<sup>1</sup>Heinrich Müller (1820-1864): A German anatomist (Wurzburg).

**FIG. 13-10.** The optic cup and lens vesicle in a human embryo during the fifth week. Note the optic fissure and the developing central vessels of the retina (hyaloid vessels).

backward as the optic tracts to the thalamus and midbrain.

**CRYSTALLINE LENS.** The crystalline lens is developed from the lens vesicle, which recedes within the margin of the cup and becomes separated by mesoderm from the overlying ectoderm. The cells forming the posterior wall of the vesicle lengthen and are converted into the lens fibers, which grow forward and fill the cavity of the vesicle (Fig. 13-11). The cells forming the anterior wall retain their cellular character and form the epithelium on the anterior surface of the adult lens.

**HYALOID ARTERY.** A capillary net continuous with the primitive choroid net enters the choroid fissure. As the fissure closes, connections with the choroid net are cut off except at the edge of the cup. The vessel enclosed in the optic stalk is the hyaloid artery. Its branches surround the deep surface of the lens and drain into the choroid net at the margin of the cup. As the vitreous body increases, the hyaloid supplies branches to it. By the second month, the lens is invested by a vascular mesodermal capsule, the **capsula vasculosa lentis**. The blood vessels supplying the posterior part of this capsule are derived from the hyaloid artery; those for the

anterior part, from the anterior ciliary arteries. The portion of the capsule that covers the front of the lens is named the **pupillary membrane**. By the sixth month all the vessels of the capsule have atrophied except the hyaloid artery, which disappears during the ninth month; the position of this artery is indicated in the adult by the hyaloid canal, which extends from the optic disc to the posterior surface of the lens. With the loss of its blood vessels, the capsula vasculosa lentis disappears, but sometimes the pupillary membrane persists at birth, giving rise to the condition termed congenital atresia of the pupil.

**CENTRAL ARTERY OF THE RETINA.** By the fourth month, branches of the hyaloid artery and veins that have developed during the third month begin to spread out in the retina and reach the ora serrata by the eighth month. After atrophy of the vitreous part of the hyaloid vessels, the proximal part in the optic nerve and retina becomes the central artery of the retina.

**CHOROID.** The choroid is analogous to the leptomeninges of the brain and spinal cord. It develops from mesenchyme between the sclera (dura) and the optic cup (an extension of the brain wall). The mesenchyme is in-

**FIG. 13-11.** Horizontal section through the eye of an 18-day-old rabbit embryo. 30  $\times$ . (Kölliker.)

vaded by capillaries from the ciliary vessels. They form a rich plexus over the outer surface of the optic cup and connect with the hyaloid capillary plexus in the pupillary region. The mesenchyme forms a loose network of fibroblasts, pigmented cells, and collagenous fibrils, partially separated by mesothelial-lined, fluid-containing spaces.

**CANAL OF SCHLEMM.** The canal of Schlemm<sup>1</sup> (sinus venosus sclerae) and the circular vessels of the iris develop from the anterior extension of the plexus of the choroid. The former is analogous to a venous sinus of the dura mater; the anterior chamber is analogous to the subarachnoid spaces. The drainage of aqueous humor by way of the pectinate villi into the canal of Schlemm is analogous to the drainage of the subarachnoid fluid by way of the arachnoid granulations into the dural sinuses.

<sup>1</sup>Friedrich S. Schlemm (1795-1858): A German anatomist (Berlin).

**VITREOUS BODY.** The vitreous body (Fig. 13-12) develops between the lens and the optic cup as the two structures become separated. Some authors believe that initially the retina and perhaps the lens as well play roles in the formation of the vitreous body; others believe that the retina plays the sole role; and still others believe that both retina and invading mesenchyme are involved. Fixed and stained preparations show throughout the vitreous body a delicate network of fibrils continuous with the long processes of stellate mesenchymal cells and with the retina. Later the fibrils are limited to the ciliary region, where they are supposed to form the **zonula ciliaris**.

**SCLERA.** The sclera (Fig. 13-12) is derived from the mesenchyme surrounding the optic cup. Fibroblasts form a dense layer of collagenous fibers continuous with the sheath of the optic nerve. The sclera is analogous to the dura mater.

**CORNEA.** Most of the cornea (Fig. 13-12) is

**FIG. 13-12.** Sagittal section of eye of human embryo of six weeks. (Kollmann.)

derived from mesenchyme that invades the region between the lens and ectoderm. The overlying ectoderm becomes the corneal epithelium. The endothelial (mesothelial) layer comes from mesenchymal cells that line the corneal side of the cleft (anterior chamber), which develops between the cornea and pupillary membrane. The factors responsible for the transparency of the cornea are unknown.

**ANTERIOR CHAMBER.** The anterior chamber of the eye appears as a cleft in the mesoderm separating the lens from the overlying ectoderm. The layer of mesoderm anterior to the cleft forms the substantia propria of the cornea, that posterior to the cleft forms the stroma of the iris and the pupillary membrane.

**PUPILLARY MEMBRANE.** In the fetus, the pupil is closed by a delicate vascular membrane, the pupillary membrane, which divides the space in which the iris is suspended into two distinct chambers. The vessels of this membrane are derived partly from those of the capsule of the margin of the iris and partly from those of the capsule of the lens; they have a looped arrangement and converge toward each other without anastomosing. About the sixth month, the membrane begins to disappear by absorption from the center toward the circumference, and at birth only a few fragments are present; in exceptional cases it persists.

The fibers of the **ciliary muscle** are derived from the mesoderm, but those of the sphincter and dilatator pupillary muscles are of ectodermal origin, being developed from the cells of the pupillary part of the optic cup.

**EYELIDS.** The eyelids are formed as small cutaneous folds (Figs. 13-11; 13-12) which, about the middle of the third month, come together and unite in front of the cornea. They remain united until about the end of the sixth month.

**LACRIMAL APPARATUS.** The **lacrimal sac** and **nasolacrimal duct** develop from a thickening of the ectoderm in the groove known as the **nasoöptic furrow**, between the lateral nasal and maxillary processes. This thickening forms a solid cord of cells that sinks into the mesoderm; during the third month the central cells of the cord break down, and a lumen, the nasolacrimal duct, is established. The lacrimal ducts arise as buds from the upper part of the cord of cells and secondar-

ily establish openings (*puncta lacrimalia*) on the margins of the lids. The **epithelium** of the cornea and conjunctiva, and that which lines the ducts and alveoli of the lacrimal gland, is of ectodermal origin, as are also the **eyelashes** and the lining cells of the glands that open on the lid margins.

## BULB OF THE EYE

The bulb of the eye is composed of segments of two spheres of different sizes. The transparent anterior segment, the cornea, is from a small sphere and forms about one-sixth of the bulb. The opaque posterior segment is from a larger sphere and forms about five-sixths of the bulb. The term **anterior pole** is applied to the central point of the anterior curvature of the bulb, and **posterior pole**, to the central point of its posterior curvature; a line joining the two poles forms the **optic axis**. The axes of the two bulbs are nearly parallel, and therefore do not correspond to the axes of the orbits, which diverge lateralward. The optic nerves follow the direction of the axes of the orbits and therefore are not parallel; each leaves its eyeball 3 mm to the nasal side and a little below the level of the posterior pole. The transverse and anteroposterior diameters of the bulb are somewhat greater than its vertical diameter; the former amounts to about 24 mm and the latter, to about 23.5 mm. In the female, all three diameters are rather less than those in the male. The anteroposterior diameter at birth is about 17.5 mm, and at puberty, 20 to 21 mm.

## Tunics of the Eye

The bulb is composed of three tunics: (1) an outer fibrous tunic, consisting of the **sclera** posteriorly and the **cornea** anteriorly; (2) an intermediate vascular, pigmented tunic, comprising the **choroid**, **ciliary body**, and **iris**; and (3) an internal neural tunic, the **retina** (Fig. 13-13).

## FIBROUS TUNIC

The sclera is opaque, and constitutes the posterior five-sixths of the tunic; the cornea is transparent, and forms the anterior sixth (Fig. 13-13).

FIG. 13-13. Horizontal section of the eyeball.

**SCLERA.** The sclera received its name from its density and hardness; it is a tough, inelastic membrane that maintains the size and form of the bulb. Its thicker posterior part measures 1 mm. Its *external surface* is white and smooth, except at the points at which the recti and obliqui muscles are inserted. Its anterior part is covered by the conjunctival membrane; the rest of the surface is separated from the fascia bulbi (capsule of Tenon<sup>1</sup>) by the loose connective tissue of a fascial cleft (see p. 1307), which permits rotation of the eyeball within the fascia.

Its *inner surface* is brown and marked by grooves, in which the ciliary nerves and vessels are lodged; it is loosely attached to the pigmented suprachoroid lamina of the choroid. Posteriorly it is pierced by the optic nerve, and is continuous through the fibrous sheath of this nerve with the dura mater.

The optic nerve passes through the **lamina cribrosa sclerae** (Fig. 13-14), in which minute orifices transmit the neural filaments, and the fibrous septa dividing them from one

another are continuous with those that separate the bundles of nerve fibers. One of these openings, larger than the rest and occupying the center of the lamina, transmits the central artery and vein of the retina. Around the exit of the optic nerve are numerous small apertures for the transmission of the ciliary vessels and nerves, and about midway between the cribrosa and the sclerocorneal junction are four or five large apertures from the transmission of the **vorticose veins**.

The sclera is directly continuous with the cornea anteriorly, the line of union being termed the **sclerocorneal junction**. Near the junction, the inner surface of the sclera projects into a circular ridge called the **scleral spur**, to which the ciliary muscle and the iris are attached. Anterior to this ridge is a circular depression, the scleral sulcus, which is crossed by trabecular tissue that separates the angle of the anterior chamber from the canal of Schlemm. The spaces of the trabecular tissue (spaces of Fontana<sup>2</sup>) connect on one side with the anterior chamber of the eye and on the other with the pectinate villi.

<sup>1</sup>Jacques René Tenon (1724-1816): A French surgeon and pathologist (Paris).

<sup>2</sup>Felice Fontana (1720-1805): An Italian physiologist and philosopher (Pisa and Florence).

**Fig. 13-14.** The terminal portion of the optic nerve as it traverses the lamina cribrosa of the sclera.

The aqueous humor filters through the walls of the villi into the canal of Schlemm.

**CORNEA.** The cornea, the transparent part of the external tunic, is almost circular in outline, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly and projects like a dome beyond the sclera. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, being more pronounced in youth than in advanced life. The cornea is dense and of uniform thickness throughout; its posterior circumference is perfectly circular in outline, and exceeds the anterior slightly in diameter. Immediately anterior to the sclerocorneal junction the cornea bulges inward as a thickened rim.

#### VASCULAR TUNIC

The vascular tunic (*uvea*) (Figs. 13-15; 13-16; 13-17) of the eye is composed of the choroid, the ciliary body, and the iris.

The choroid invests the posterior five-sixths of the bulb and extends as far anteriorly as the ora serrata of the retina. The ciliary body connects the choroid to the circumference of the iris. The iris is a circular diaphragm behind the cornea and presents near its center a rounded aperture, the **pupil**.

**CHOROID.** The choroid is a thin, highly

vascular membrane, dark brown or chocolate-colored, investing the posterior five-sixths of the bulb; it is pierced posteriorly by the optic nerve, and in this location is firmly adherent to the sclera. Its outer surface is loosely connected by the lamina suprachorioidea with the sclera; its inner surface is attached to the pigmented layer of the retina.

**CILIARY BODY.** The ciliary body extends from the ora serrata of the retina to the outer edge of the iris and the sclerocorneal junction. It consists of the thickened vascular tunic of the eye and the ciliary muscle. Its

**Fig. 13-15.** The arteries of the choroid and iris. The greater part of the sclera has been removed. (Enlarged.)

FIG. 13-16. The veins of the choroid. (Enlarged.)

inner surface is covered by the thin, pigmented **ciliary part of the retina**. The suspensory ligament of the lens is attached to the ciliary body. The ciliary body comprises two zones, the **orbiculus ciliaris** and the **ciliary processes** (Fig. 13-18).

The **orbiculus ciliaris** is 4 mm wide and extends from the ora serrata to the ciliary processes. Its thickness increases as it approaches the ciliary processes owing to the

increase in thickness of the ciliary muscle. The choroid layer is thicker here than over the optical part of the retina. Its inner surface presents numerous small, radially arranged ridges, the **ciliary processes**.

The **ciliary processes** are formed by the inward folding of the various layers of the choroid, i.e., the choroid proper and the lamina basalis; the layers are received between corresponding foldings of the suspensory ligament of the lens. The ciliary processes are arranged radially on the posterior surface of the iris, forming a sort of frill around the margin of the lens (Fig. 13-18). Their numbers vary from 60 to 80; the larger ones are about 2.5 mm long, and the smaller ones, consisting of about one-third of the entire number, are situated in spaces between the larger processes, but with no regular arrangement. They are attached by their periphery to three or four ridges of the orbiculus ciliaris and are continuous with the layers of the choroid. Their other extremities are free and rounded, and are directed toward the circumference of the lens. Anteriorly, they are continuous with the periphery of the iris. Their posterior surfaces are connected with the suspensory ligament of the lens.

The **ciliaris muscle** (ciliary muscle) consists of unstriated fibers. It forms a grayish, semitransparent, circular band, about 3 mm broad, on the outer surface of the anterior part of the choroid. It is thickest anteriorly and consists of two sets of fibers, **meridional**

FIG. 13-17. The choroid and iris. (Enlarged.)

FIG. 13-18. Interior of anterior half of bulb of eye.

and **circular**. The meridional fibers, much more numerous than the circular fibers, arise from the posterior margin of the scleral spur; they run posteriorly and are attached to the ciliary processes and orbiculus ciliaris. The circular fibers are internal to the meridional ones, and in a meridional section they appear as a triangular zone behind the filtration angle and close to the circumference of the iris. They are well developed in hypermetropic eyes, but are rudimentary or absent in myopic eyes. The ciliaris muscle is the chief agent in accommodation, i.e., in adjusting the eye to the vision of near objects. When it contracts, it draws the ciliary processes centripetally, relaxes the suspensory ligament of the lens, and thus allows the lens to become more convex.

**IRIS.** The iris has received its name from its various colors in different individuals. It is a circular, contractile disc suspended in the aqueous humor between the cornea and lens; it is perforated a little to the nasal side of its center by a circular aperture, the **pupil**. At its periphery it is continuous with the ciliary body, and it is also connected with the posterior elastic lamina of the cornea by means of the pectinate ligament. Its flat surfaces are anterior, toward the cornea, and posterior, toward the ciliary processes and lens. The iris divides the space between the lens and the cornea into an anterior and a posterior chamber. The **anterior chamber** of the eye is bound anteriorly by the posterior surface of the cornea and posteriorly by the iris and the central part of the lens. The **posterior chamber** is a narrow cleft posterior to the peripheral part of the iris and anterior to the suspensory ligament of the lens and the ciliary processes (Fig. 13-13). In the adult, the two chambers communicate through the pupil, but in the fetus, until the seventh month, they are separated by the pupillary membrane (p. 1288).

#### INTERNAL TUNIC

The **internal tunic** is a continuous membrane, but has a posterior nervous part, the **retina** proper, and an anterior non-neural part, the **pars ciliaris** and **pars iridica retinae**.

**RETINA.** The retina is a delicate neural membrane upon which the images of external objects are received. Its outer surface is in contact with the choroid; its inner surface,

with the vitreous body. Posteriorly, it is continuous with the optic nerve. It gradually diminishes in thickness anteriorly and extends nearly as far as the ciliary body, where it appears to end in a jagged margin, the **ora serrata**. Here the neural tissue of the retina ends, but a thin prolongation of the membrane extends anteriorly over the back of the ciliary processes and iris, forming the **pars ciliaris retinae** and **pars iridica retinae** already referred to. This forward prolongation consists of the pigmented layer of the retina together with a stratum of columnar epithelium. The retina is soft and semitransparent. It has a purple tint in the fresh state, owing to the presence of a coloring material named **rhodopsin** or **visual purple**, but it soon becomes clouded, opaque, and bleached when exposed to sunlight. Exactly in the center of the posterior part of the retina, corresponding to the optical axis of the eye and at a point in which the sense of vision is most perfect, is an oval yellowish area, the **macula**; in the macula is a central depression, the **fovea centralis** (Fig. 13-18). At the fovea centralis the retina is exceedingly thin, and the dark color of the choroid is distinctly seen through it. About 3 mm to the nasal side of the macula is the **optic disc**, which marks the exit of the optic nerve. A depression in the center of the disc, the **porus opticus**, marks the point of entrance of the central retinal artery. The disc is the only part of the surface of the retina that is insensitive to light, and it is termed the **blind spot** (Fig. 13-19).

#### Structure of the Tunics of the Bulb

##### STRUCTURE OF THE SCLERA

The sclera is formed of bundles and laminae of collagenous fibers intermixed with fine elastic fibers, fibroblasts, and other connective tissue cells. Its vessels are not numerous, the capillaries being small and uniting at long and wide intervals. Its nerves are derived from the ciliary nerves.

##### STRUCTURE OF THE CORNEA

The cornea consists of five layers: (1) the **corneal epithelium**, continuous with that of the conjunctiva; (2) the **anterior lamina**; (3) the **substantia propria**; (4) the **posterior lam-**

**Fig. 13-19.** Interior of posterior half of right eye as viewed through an ophthalmoscope. The distribution of central vessels of the retina is shown (veins darker than arteries) and their relation to the optic disc. The area of most acute vision, the macula, is shown. (Eycleshymer and Jones.)

ina; and (5) the **endothelium** (mesothelium) of the anterior chamber (Fig. 13-20).

The **corneal epithelium** (anterior layer) covers the front of the cornea and consists of several layers of cells. The cells of the deepest layer are columnar; then follow two or three layers of polyhedral cells, the majority of which are prickle cells similar to those found in the stratum mucosum of the cuticle. Lastly, there are three or four layers of squamous cells, with flat nuclei.

The **anterior lamina** (anterior limiting layer; Bowman's membrane) consists of closely interwoven fibrils, similar to those found in the substantia propria but containing no corneal corpuscles. It may be regarded as a condensed part of the substantia propria.

The **substantia propria corneae** is fibrous, tough, unyielding, and perfectly transparent. It is composed of about 60 flat superimposed lamellae made up of bundles of modified connective tissue, the fibers of which are directly continuous with those of the sclera. The fibers of each lamella are for the most part parallel with one another, but at right

angles to those of adjacent lamellae, and frequently pass from one lamella to the next. The lamellae are held together by an interstitial cement substance, except for the **corneal spaces** which contain the **corneal corpuscles**, modified fibroblasts resembling the space in form, but not entirely filling them.

The **posterior elastic lamina** (membrane of Descemet<sup>1</sup>; membrane of Demours<sup>2</sup>) covers the posterior surface of the substantia propria. It is an elastic, transparent, homogeneous membrane of extreme thinness, which is not rendered opaque by either water, alcohol, or acids. When stripped from the substantia propria it curls up, or rolls upon itself with the attached surface innermost.

At the margin of the cornea, the posterior elastic lamina breaks up into fibers that form the trabecular tissue already described. Some of the fibers of this trabecular tissue are continued into the substance of the iris,

<sup>1</sup>Jean Descemet (1732-1810): A French anatomist and surgeon (Paris).

<sup>2</sup>Pierre Demours (1702-1795): A French ophthalmologist (Paris).

**FIG. 13-20.** Vertical section of human cornea from near the margin. (Waldeyer.) Magnified. 1. Epithelium. 2. Anterior lamina. 3. Substantia propria. 4. Posterior elastic lamina. 5. Endothelium of the anterior chamber. a, Oblique fibers in the anterior layer of the substantia propria. b, Lamellae, the fibers of which are cut across, producing a dotted appearance. c, Corneal corpuscles appearing fusiform in section. d, Lamellae, the fibers of which are cut longitudinally. e, Transition to the sclera, with more distinct fibrillation, and surmounted by a thicker epithelium. f, Small blood vessels cut across near the margin of the cornea.

forming the **pectinate ligament of the iris**, while others are connected with the forepart of the sclera and choroid.

The **endothelium** of the anterior chamber (posterior layer; *corneal endothelium*) is a mesothelial, rather than an endothelial, layer that covers the posterior surface of the elastic lamina. It is reflected onto the front of the iris, and also lines the spaces of the angle of the iris. It consists of a single stratum of polygonal, flattened, nucleated cells.

**VESSELS AND NERVES.** The cornea is a nonvascular structure. The capillary vessels, which end in loops at its circumference, are derived from the anterior ciliary arteries. Lymphatic vessels have not yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these channels are lined by an endothelium.

The **nerves** are numerous and are derived from the ciliary nerves. Around the periphery of the cornea they form an **annular plexus**, from which fibers enter the substantia propria. They lose their myelin sheaths and ramify throughout its substance in a delicate network, and their terminal filaments form a firm and close plexus on the surface of the cornea proper, beneath the epithelium. This is termed the **subepithelial plexus**, and from it fibrils are given off that ramify between the epithelial cells, forming an **intraepithelial plexus**.

### STRUCTURE OF THE CHOROID

The choroid consists mainly of a dense capillary plexus and of small arteries and veins that carry blood to and from this plexus. On its external surface is a thin membrane, the **lamina suprachoroidea**, composed of delicate nonvascular lamellae—each lamella consisting of a network of fine elastic fibers, among which are branched pigment cells. The potential spaces between the lamellae are lined by mesothelium and open freely into the **perichoroidal space**.

Internal to this lamina is the **choroid proper**, consisting of two layers: an outer layer, composed of small arteries and veins with pigment cells interspersed between them; and an inner layer, consisting of a capillary plexus.

The **outer layer** (*lamina vasculosa*) consists partly of the larger branches of the short ciliary arteries that run between the veins before they bend inward to end in the capillaries, but primarily this layer is formed of veins, named the **venae vorticosae** from their arrangement (Figs. 13-16; 13-17). The veins converge to four or five equidistant trunks, which pierce the sclera midway between the sclerocorneal junction and the exit of the optic nerve. Interspersed between the vessels are dark, star-shaped pigment cells, the processes of which, communicating with those of neighboring cells, form a delicate network or stroma, which loses its pigmented character toward the inner surface of the choroid.

The **inner layer** (*lamina choriocapillaris*) consists of an exceedingly fine capillary

plexus formed by the short ciliary vessels; the network is closer and finer in the posterior than in the anterior part of the choroid. About 1.25 cm behind the cornea, the meshes of the plexus become larger and are continuous with those of the ciliary processes. These two laminae are connected by a **stratum intermedium**, which consists of fine elastic fibers. On the inner surface of the lamina choriocapillaris is a thin, structureless, or faintly fibrous membrane called the **lamina basalis**; it is closely connected with the stroma of the choroid and separates it from the pigmented layer of the retina.

One of the functions of the choroid is to provide nutrition for the retina and to convey vessels and nerves to the ciliary body and iris.

**TAPETUM.** This name is applied to the outer and posterior part of the choroid, which in many animals has an iridescent appearance.

#### STRUCTURE OF THE CILIARY PROCESSES

The structure of the ciliary processes (Fig. 13-18) is similar to that of the choroid, but the vessels are larger and have chiefly a longitudinal direction. Their posterior surfaces are covered by a bilaminar layer of black pigment cells, which is continued anteriorly from the retina and is named the **pars ciliaris retinae**. In the stroma of the ciliary processes are also stellate pigment cells, but these are not as numerous as in the choroid itself.

#### STRUCTURE OF THE IRIS

The iris is composed of the following structures:

1. A layer of flat mesothelial cells is placed on a delicate hyaline basement membrane on the anterior surface. This layer is continuous with the mesothelium covering the posterior elastic lamina of the cornea, and in individuals with dark-colored irises, the cells contain pigment granules.

2. The **stroma** of the iris consists of fibers and cells. The former are made up of delicate collagenous bundles. A few fibers at the circumference of the iris have a circular direction, but the majority radiate toward the pupil, forming delicate meshes in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue are numerous branched cells with fine

processes. In dark eyes, many of these cells contain pigment granules, but in blue eyes and the eyes of albinos, they are unpigmented.

3. The **muscular fibers** are involuntary and consist of circular and radiating fibers. The **circular fibers** form the **sphincter pupillae**; they are arranged in a narrow band about 1 mm wide that surrounds the margin of the pupil toward the posterior surface of the iris. The fibers near the free margin are closely aggregated; those near the periphery of the band are somewhat separated and form incomplete circles. The **radiating fibers** form the **dilatator pupillae**; they converge from the circumference toward the center and blend with the circular fibers near the margin of the pupil.

4. The posterior surface of the iris has a deep purple tint, being covered by two layers of pigmented columnar epithelium that are continuous at the periphery of the iris with the pars ciliaris retinae. This pigmented epithelium is named the **pars iridica retinae**.

The color of the iris is produced by the reflection of light from dark pigment cells underlying a translucent tissue, and it is determined, therefore, by the amount of the pigment and its distribution throughout the texture of the iris. The number and the situation of the pigment cells differ in different irises. In the albino, pigment is absent; in the various shades of blue eyes, the pigment cells are confined to the posterior surface of the iris, whereas in gray, brown, and black eyes, pigment is found also in the cells of the stroma and in those of the endothelium on the front of the iris.

**CLINICAL NOTE.** The iris may be absent, either in part or altogether, as a congenital condition, and in some instances the pupillary membrane persists, although it is rarely complete. The iris may be the seat of a malformation termed a *coloboma*, which consists of a deficiency or cleft, due in a great number of cases to an arrest in development. In these cases the cleft is found at the lower aspect, extending directly downward from the pupil, and the gap frequently extends through the choroid to the porus opticus. In some rare cases the gap is found in other parts of the iris, and is not then associated with any deficiency of the choroid.

**VESSELS AND NERVES.** The arteries of the iris are derived from the long and anterior ciliary arteries and from the vessels of the ciliary processes (see p. 1292). Each of the two long ciliary arteries, having reached the attached margin of the iris, divides into an upper and lower branch. These anastomose with

corresponding branches from the opposite side and thus encircle the iris. Into this vascular circle, the **circulus arteriosus major**, the anterior ciliary arteries pour their blood, and from it vessels converge to the free margin of the iris, where they communicate to form a second circle, the **circulus arteriosus minor** (Fig. 13-21).

The **nerves of the choroid and iris** (Fig. 13-16) are the long and short ciliary nerves; the former are branches of the nasociliary nerve, and the latter are branches of the ciliary ganglion. They pierce the sclera around the entrance of the optic nerve, run forward in the perichoroidal space, and supply the blood vessels of the choroid. After reaching the iris, they form a plexus around its attached margin; from this are derived unmyelinated fibers that end in the sphincter and dilatator pupillae. Other fibers from the plexus end in a network on the anterior surface of the iris. The fibers, derived through the motor root of the ciliary ganglion from the oculomotor nerve, supply the sphincter pupillae, while those derived from the sympathetic root supply the dilatator pupillae.

### STRUCTURE OF THE RETINA

The retina consists of an outer pigmented layer and an inner neural stratum or retina proper (Figs. 13-22; 13-23).

**RETINA PROPER.** The neural structures of the retina proper are supported by a series of nonneural or sustentacular fibers. In histologic sections made perpendicularly to the surface of the retina, ten layers are identified and named from within outward as follows:

**Fig. 13-22.** Section of human retina. e.l.m., external limiting membrane; g.l., ganglionic layer; i.l.m., internal limiting membrane; i.n., inner nuclear layer; i.p., inner plexiform layer; o.n., outer nuclear layer; o.p., outer plexiform layer; pig., pigment cell layer; r.c., layer of rods and cones; s.o., stratum opticum. 500  $\times$ . (Redrawn from Sobotta.)

1. Internal limiting membrane
2. Stratum opticum, layer of nerve fibers
3. Ganglion cell layer
4. Inner plexiform layer
5. Inner nuclear layer
6. Outer plexiform layer
7. Outer nuclear layer
8. External limiting membrane
9. Layer of rods and cones
10. Pigmented layer

1. The **internal limiting membrane** is a thin cribriform layer formed by the sustentacular fibers (p. 1301).

2. The **stratum opticum** or **layer of nerve fibers** is formed by the expansion of the fibers of the optic nerve; it is thickest near the **porus opticus**, gradually diminishing toward the **ora serrata**. As the nerve fibers pass through the lamina cribrosa sclerae, they lose their myelin sheaths and continue onward through the choroid and retina as simple axons. When they reach the internal surface of the retina, they radiate as a group of bundles from their point of entrance, and in many places they are arranged in plexuses. Most of the fibers are centripetal and are the direct continuations of the axons of the cells of the ganglionic layer, but a few of them are centrifugal and ramify in the inner plexiform and inner nuclear layers, where they end in enlarged extremities.

**Fig. 13-21.** Iris, anterior view.

FIG. 13-23. Plan of retinal neurons. (After Cajal.)

3. The **ganglion cell layer** consists of a single layer of large ganglion cells, except in the macula, where there are several strata. The cells are somewhat flask-shaped; the rounded internal surface of each rests on the stratum opticum and sends an axon into the fiber layer. From the opposite end numerous dendrites extend into the inner plexiform layer, where they branch and form flat arborizations at different levels. The ganglion cells vary much in size, and the dendrites of the smaller ones usually arborize in the inner plexiform layer as soon as they enter it, while those of the larger cells ramify close to the inner nuclear layer.

4. The **inner plexiform layer** is made up of a dense reticulum of minute fibrils formed by the interlacement of the dendrites of the ganglion cells with those of the cells of the inner nuclear layer. Within this reticulum, a few branched spongioblasts are embedded.

5. The **inner nuclear layer** is made up of closely packed cells, of which there are three varieties: bipolar cells, horizontal cells and amacrine cells.

The **bipolar cells**, by far the most numerous, are round or oval, and each is prolonged

into an inner and an outer process. They are divisible into rod bipolars and cone bipolars. The inner processes of the **rod bipolars** run through the inner plexiform layer and arborize around the bodies of the cells of the ganglionic layer; their outer processes end in the outer plexiform layer in tufts of fibrils around the button-like ends of the inner processes of the rod granules. The inner processes of the **cone bipolars** ramify in the inner plexiform layer in contact with the dendrites of the ganglionic cells.

The **horizontal cells** lie in the outer part of the inner nuclear layer and have somewhat flattened cell bodies. Their dendrites divide into numerous branches in the outer plexiform layer, while their axons run horizontally for some distance and finally ramify in the same layer.

The **amacrine cells** are in the inner part of the inner nuclear layer and are so named because it has not yet been shown that they possess axons. Their dendrites ramify extensively in the inner plexiform layer.

The cell bodies and nuclei of the sustentacular fibers are in this layer.

6. The **outer plexiform layer** is much thin-

ner than the inner layer but, like it, consists of a dense network of minute fibrils derived from the processes of the horizontal cells of the preceding layer and the outer processes of the rod and cone bipoplar cells, which ramify in it, forming arborizations around the enlarged ends of the rod fibers and with the branched foot plates of the cone fibers.

7. The **outer nuclear layer**, like the inner nuclear layer, contains strata of oval cell bodies. The latter are of two types: rod or cone nuclei, so named because they are connected respectively with the rods and cones of the next layer. The **rod nuclei** are much more numerous and are placed at different levels throughout the layer. Prolonged from either extremity of each cell is a fine process. The outer process is continuous with a sin-

gle rod of the layer of rods and cones; the inner process ends in the outer plexiform layer in an enlarged extremity and is embedded in the tuft into which the outer processes of the rod bipolar cells break up. In its course it has numerous varicosities.

The **cone nuclei**, fewer in number than the rod nuclei, are placed close to the external limiting membrane, through which they are continuous with the cones of the layer of rods and cones. They contain a piriform nucleus that almost completely fills the cell. From the inner extremity, a thick process passes into the outer plexiform layer, and there expands into a pyramidal enlargement or foot plate from which numerous fine fibrils are given off and come in contact with the outer processes of the cone bipolars.

FIG. 13-24. A horizontal section through half of the anterior part of the eyeball.

8. The **external limiting membrane** is formed by the sustentacular cells (see below).

9. The **layer of rods and cones** (Jacob's membrane<sup>1</sup>).—The elements composing this layer are of two types, **rods** and **cones**, the former being much more numerous than the latter, except in the macula (Figs. 13-22; 13-23).

The **rods** are cylindrical, 40 to 60  $\mu$  long, 2  $\mu$  thick and arranged perpendicular to the surface. Each rod consists of an outer and an inner segment of about equal length. The outer segment is more slender than the inner segment, is strongly refractive and has transverse striae; it tends to break up into a number of thin discs superimposed on one another. It also exhibits faint longitudinal markings. The inner part of the inner segment is indistinctly granular and is called the myoid; its outer part presents a longitudinal striation and represents the ellipsoid, which is composed of fine, bright, highly refracting fibrils. The visual purple or **rhodopsin**, found in the outer segments, gives a purple or reddish color in a dark-adapted eye, and is the pigment for detection of low light intensity.

The **cones** are conical or flask-shaped; their broad ends rest upon the external limiting membrane, and the narrow, pointed extremity is turned to the choroid. Like the rods, each is made up of two segments, outer and inner; the outer segment is a short conical process, which, like the outer segment of the rod, exhibits transverse striae. The inner segment resembles the inner segment of the rods in structure, but it has a larger, thicker ellipsoid and a bulging deep granular part. The pigment in the outer segment of the cones is **iodopsin**, which is for color vision.

10. The **pigmented layer** consists of a single stratum of cells. When viewed from the outer surface, these cells are smooth and hexagonal; when seen in section, each cell consists of an outer nonpigmented part containing a large oval nucleus and an inner pigmented portion that extends as a series of straight thread-like processes between the rods, especially when the eye is exposed to light. In the eyes of albinos, the cells of this layer have no pigment.

#### SUPPORTING FRAMEWORK OF THE RETINA.

The neural layers of the retina are connected by a supporting framework formed by the **sustentacular fibers of Müller**; these fibers pass through all the neural layers except that of the rods and cones. Each begins on the inner surface of the retina by an expanded, often forked base, which sometimes contains a spheroidal body that stains deeply with hematoxylin. The edges of the bases of adjoining fibers unite to form the **internal limiting membrane**. As the fibers pass through the nerve fiber and ganglionic layers, they give off a few lateral branches; in the inner nuclear layer they give off numerous lateral processes for the support of the bipolar cells, while in the outer nuclear layer they form a network around the rod and cone fibrils, and unite to form the **external limiting membrane** at the bases of the rods and cones. At the level of the inner nuclear layer, each sustentacular fiber contains a clear oval nucleus.

**MACULA AND FOVEA CENTRALIS.** In the macula, the nerve fibers are wanting as a continuous layer, the ganglionic layer consists of several strata of cells, and the rods are lacking. The cones are longer and narrower than in other parts, and in the outer nuclear layer there are only cone nuclei, the processes of which are very long and arranged in curved lines.

In the fovea centralis, the only parts present are (1) the cones; (2) the outer nuclear layer, the cone fibers of which are directed almost horizontally; (3) an exceedingly thin inner plexiform layer. The pigmented layer is thicker and its pigment more pronounced than elsewhere. The color of the macula seems to imbue all the layers except that of the cones; it is a rich yellow and deepest toward the center of the macula.

**ORA SERRATA.** At the **ora serrata** (Fig. 13-18), the neural layers of the retina end abruptly, and the retina continues onward as a single layer of columnar cells covered by the pigmented layer. This double layer is known as the **pars ciliaris retinae**, and can be traced forward from the ciliary processes on to the back of the iris, where it is termed the **pars iridica retinae**.

**VESSELS.** The **central retinal artery** (Fig. 13-19) and its accompanying vein pierce the optic nerve and enter the bulb of the eye through the porus

<sup>1</sup>Arthur Jacob (1790-1874): Irish ophthalmologist and anatomist (Dublin).

opticus. The artery immediately bifurcates into an upper and a lower branch, and each of these again divides into a medial or nasal and a lateral or temporal branch. These branches first run between the hyaloid membrane and the neural layer, but they soon enter the neural layer and pass anteriorly, dividing dichotomously. From these branches a minute capillary plexus is given off that does not extend beyond the inner nuclear layer. The macula receives two small branches (superior and inferior macular arteries) from the temporal branches and small twigs directly from the central artery; these do not, however, reach as far as the fovea centralis, which has no blood vessels. The branches of the central retinal artery do not anastomose with each other—in other words, they are terminal arteries. In the fetus, a small vessel, the *hyaloid artery*, passes forward as a continuation of the central retinal artery through the vitreous humor to the posterior surface of the capsule of the lens.

### REFRACTING MEDIA

The refracting media are five:

- Cornea (see p. 1292)
- Aqueous humor
- Vitreous body
- Zonula ciliaris
- Crystalline lens

#### Aqueous Humor

The aqueous humor fills the anterior and posterior chambers. It is small in quantity, has an alkaline reaction, and consists mainly of water. The aqueous humor is secreted by the ciliary process. The fluid passes through the posterior chamber and the pupil into the anterior chamber. From the angle of the anterior chamber it passes into the spaces of Fontana to the pectinate villi, through which it is filtered into the venous canal of Schlemm.

#### Vitreous Body

The vitreous body fills the concavity of the pars optica retinae, to which it is firmly adherent, especially at the ora serrata. It is transparent, semigelatinous, and is hollowed anteriorly for the lens. Some indications of the hyaloid canal between the optic nerve and lens may persist.

No blood vessels penetrate the vitreous body, so that its nutrition must be carried on by vessels of the retina and ciliary processes, situated upon its exterior.

#### Zonula Ciliaris

The zonula ciliaris (zonule of Zinn,<sup>1</sup> suspensory ligament of the lens) consists of a series of straight fibrils that radiate from the ciliary body to the lens. It is attached to the capsule of the lens a short distance anterior to its equator. Scattered delicate fibers are also attached to the region of the equator itself. This ligament retains the lens in position, and is relaxed by the contraction of the meridional fibers of the ciliary muscle, so that the lens is allowed to become more convex. Posterior to the suspensory ligament there is a sacculated canal, the **spatia zonularia** (canal of Petit<sup>2</sup>), which encircles the equator of the lens; it can be easily inflated through a fine blowpipe inserted under the suspensory ligament.

#### Crystalline Lens

The crystalline lens, enclosed in its capsule, is situated immediately between the iris and the vitreous body and is encircled by the ciliary processes, which slightly overlap its margin.

The **capsule of the lens** (*capsula lentis*) is a transparent, structureless membrane that closely surrounds the lens and is thicker in front than behind. It is brittle but highly elastic, and when ruptured the edges roll up, with the outer surface innermost. It rests in the hyaloid fossa in the anterior part of the vitreous body posteriorly and is in contact with the free border of the iris anteriorly, but recedes from it at the circumference, thus forming the posterior chamber of the eye. It is retained in its position chiefly by the suspensory ligament of the lens, already described.

The **lens** is a transparent, biconvex body; the convexity of its anterior surface is less than that of its posterior surface. The central points of these surfaces are termed, respectively, the **anterior** and **posterior poles**; a line connecting the poles constitutes the **axis** of the lens, while the marginal circumference is termed the **equator**.

<sup>1</sup>Johann Gottfried Zinn (1727–1759): A German physician and botanist (Göttingen).

<sup>2</sup>François Pourfour du Petit (1664–1741): French surgeon and anatomist (Paris).

### STRUCTURE OF THE LENS

The lens is made up of a soft cortical substance and a firm, central part, the **nucleus** (Fig. 13-25). Faint lines (*radii lentis*) radiate from the poles to the equator. In the adult there may be six or more of these lines, but in the fetus there are only three, and they diverge from each other at angles of  $120^\circ$  (Fig. 13-26). On the anterior surface, one line ascends vertically and the other two diverge downward; on the posterior surface, one ray descends vertically and the other two diverge upward. They correspond with the free edges of an equal number of septa that are composed of an amorphous substance. These septa dip into the substance of the lens and mark the interruptions of a series of concentrically arranged laminae (Fig. 13-25). Each lamina is built up of a number of hexagonal, ribbon-like lens fibers, the edges of which are more or less serrated. The serrations fit between those of neighboring fibers, while the ends of the fibers come into apposition at the septa. The fibers run in a curved manner from the septa on the anterior surface to those on the posterior surface. No fibers pass from pole to pole; they are arranged in such a way that those beginning near the pole on one surface of the lens end near the peripheral extremity of the plane on the other, and vice versa. The fibers of the outer layers of the lens are nucleated, and together they form a nuclear layer, most distinct toward the equator. The anterior surface of the lens is covered by a layer of transparent, columnar, nucleated epithelium. At the equator the cells become elongated, and their gradual transition into lens fibers can be traced (Fig. 13-27).

In the fetus, the lens is nearly spherical, and has a slightly reddish tint; it is soft and breaks down readily on the slightest pres-

**Fig. 13-25.** The crystalline lens, hardened and divided. (Enlarged.)

**Fig. 13-26.** Diagram showing the direction and arrangement of the radiating lines on the front and back of the fetal lens. A, From the front. B, From the back.

sure. A small branch from the central retinal artery runs forward, as already mentioned, through the vitreous body to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network that covers the posterior surface of the capsule. The branches are continuous around the margin of the capsule with the vessels of the pupillary membrane and with those of the iris. In the adult, the lens is colorless, transparent, firm, and devoid of vessels. In old age it becomes flattened on both surfaces and slightly opaque, has an amber tint, and increases in density (Fig. 13-28).

### VESSELS AND NERVES OF THE BULB (Fig. 13-15).

The **arteries** of the eye are the long, short, and anterior ciliary arteries and the central retinal artery. They have already been described (see p. 688).

The **ciliary veins** are seen on the outer surface of the choroid and are named, because of their arrangement, the *venae vorticosae* (Fig. 13-16). The veins converge to four or five equidistant trunks that pierce the sclera midway between the sclerocorneal junction and the porus opticus. Another set of veins accompanies the anterior ciliary arteries. All these veins open into the ophthalmic veins.

The **ciliary nerves** are derived from the nasociliary nerve and from the ciliary ganglion.

### ACCESSORY ORGANS OF THE EYE

The **accessory organs of the eye** include the **ocular muscles**, the **fasciae**, the **eyebrows**, the **eyelids**, the **conjunctiva**, and the **lacrimal apparatus**.

#### Ocular Muscles

The ocular muscles are:

Levator palpebrae superioris  
Rectus superior  
Rectus inferior

**Fig. 13-27.** Section through the margin of the lens, showing the transition of the epithelium into the lens fibers. (Babuchin.)

Rectus medialis  
Rectus lateralis  
Obliquus superior  
Obliquus inferior

The **levator palpebrae superioris** (Fig. 13-29) is a thin, flat muscle arising from the

**Fig. 13-28.** Profile views of the lens at different periods of life. 1. In the fetus. 2. In adult life. 3. In old age.

inferior surface of the small wing of the sphenoid, where it is separated from the optic foramen by the origin of the rectus superior. At its origin it is narrow and tendinous, but it becomes broad and fleshy and ends anteriorly in a wide aponeurosis that splits into three lamellae. The superficial lamella blends with the superior part of the orbital septum, and is prolonged over the superior tarsus to the palpebral part of the orbicularis oculi and to the deep surface of the skin of the upper eyelid. The middle lamella, largely made up of nonstriated muscular fibers, is inserted into the superior margin of the superior tarsus, while the deepest lamella blends with an expansion from the sheath of the rectus superior and with it is attached to the superior fornix of the conjunctiva.

The four **recti** muscles (Fig. 13-30) arise from a fibrous ring (*anulus tendineus communis*) that surrounds the superior, medial, and inferior margins of the optic foramen and encircles the optic nerve (Fig. 13-31). The ring is completed by a tendinous bridge prolonged over the inferior and medial part of the superior orbital fissure and attached to a tubercle on the margin of the great wing of the sphenoid, bounding the fissure. Two specialized parts of this fibrous ring may be made out: a lower, the *ligament or tendon of Zinn*, which gives origin to the **rectus inferior**, part of the **rectus medialis**, and the lower head of origin of the **rectus lateralis**; and an upper part which gives origin to the **rectus superior**, the rest of the rectus medialis, and the upper head of the rectus lateralis. This upper band is sometimes termed the *superior tendon of Lockwood*.<sup>1</sup> Each muscle passes anteriorly in the position implied by its name, to be inserted by a tendi-

<sup>1</sup>Charles Barrett Lockwood (1856–1914): An English surgeon (London).

**Fig. 13-29.** Sagittal section of the right orbital cavity.

nous expansion into the sclera, about 6 mm from the margin of the cornea. Between the two heads of the rectus lateralis is a narrow interval through which pass the two divisions of the oculomotor nerve, the nasociliary nerve, the abducens nerve, and the ophthalmic vein. Although these muscles have a common origin and are inserted in a similar manner into the sclera, there are certain differences between their length and breadth. The rectus medialis is the broadest, the rectus lateralis the longest, and the rectus superior the thinnest and narrowest.

The **obliquus superior oculi** (*superior oblique*) is a fusiform muscle placed at the superior and medial side of the orbit. It arises immediately above the margin of the optic foramen, superior and medial to the origin of the rectus superior, and passing anteriorly, it ends in a rounded tendon that plays in a fibrocartilaginous ring or pulley attached to the trochlear fovea of the frontal bone. The contiguous surfaces of the tendon and ring are lined by a delicate synovial sheath and are enclosed in a thin fibrous

investment. The tendon bends around the pulley at more than a right angle, passes beneath the rectus superior to the lateral part of the bulb of the eye, and is inserted into the sclera, posterior to the equator of the eyeball; the insertion of the muscle lies between the rectus superior and the rectus lateralis.

The **obliquus inferior oculi** (*inferior oblique*) is a thin, narrow muscle placed near the anterior margin of the floor of the orbit. It arises from the orbital surface of the maxilla, lateral to the lacrimal groove. Passing lateralward, at first between the rectus inferior and the floor of the orbit and then between the bulb and the rectus lateralis, it is inserted into the lateral part of the sclera between the rectus superior and the rectus lateralis, near but somewhat posterior to the insertion of the obliquus superior.

**NERVES.** The levator palpebrae superioris, the obliquus inferior, and the recti superior, inferior, and medialis are supplied by the oculomotor nerve; the obliquus superior is supplied by the trochlear nerve, and the rectus lateralis, by the abducens nerve (Fig. 13-31).

FIG. 13-30. Muscles of the right orbit.

FIG. 13-31. Dissection showing origins of right ocular muscles and the nerves entering the orbit through the superior orbital fissure.

**ACTIONS.** The levator palpebrae *raises* the upper eyelid and is the direct antagonist of the orbicularis oculi. The four recti are attached to the bulb of the eye in such a manner that, acting singly, they turn its corneal surface in the direction corresponding to their names. The movement produced by the rectus superior or rectus inferior is not a simple one because the axis of the orbit, and hence their direction of pull, diverges from the median plane, causing their pull to be accompanied by a certain deviation medialward, with a slight amount of rotation. These latter movements are corrected by the obliqui; the obliquus inferior corrects the medial deviation caused by the rectus superior and the obliquus superior corrects the deviation caused by the rectus inferior. The contraction of the rectus lateralis or rectus medialis, on the other hand, produces a purely horizontal movement. If any two neighboring recti of one eye act together, they carry the globe of the eye diagonally in these directions: upward and medialward, upward and lateralward, downward and medialward, or downward and lateralward. Sometimes the corresponding recti of the two eyes act in unison, and at other times the opposite recti act together. Thus, in turning the eyes to the right, the rectus lateralis of the right eye will act in unison with the rectus medialis of the left eye, but if both eyes are directed to an object in the midline at a short distance, the two recti mediales will act in unison. The movement of circumduction, as in looking around a room, is performed by the successive actions of the four recti. The obliqui rotate the eyeball on its anteroposterior axis, the superior muscle directing the cornea downward and lateralward, and the inferior muscle directing it upward and lateral-

ward. These movements are required for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of either eye.

A layer of nonstriated muscle, the **orbitalis muscle** (of H. Müller), bridges the inferior orbital fissure.

### *Fasciae and Ligaments*

The **fascia bulbi** (*vagina bulbi*; *capsule of Tenon*) (Fig. 13-32) is a thin membrane that envelops the eyeball from the optic nerve to the ciliary region, separating it from the orbital fat and forming a socket in which it plays. Its inner surface is smooth and is separated from the outer surface of the sclera by the **periscleral fascial cleft**. This space between the fascia and sclera (*spatium intervaginale*) is continuous with the subdural and subarachnoid cavities; it is traversed by delicate bands of connective tissue that extend between the fascia and the sclera. The fascia is perforated by the ciliary vessels and nerves, and it fuses with the sheath of the optic nerve and with the sclera around the lamina cribrosa. Anteriorly it blends with the ocular conjunctiva, with which it is attached to the ciliary region of the bulb.

The fascia bulbi is prolonged over tendons

**FIG. 13-32.** Fascia bulbi (capsule of Tenon). Sagittal section, semidiagrammatic. (Redrawn from *Surgical Anatomy of the Human Body* by J. B. Deaver, P. Blakiston's Son & Co., 1926.)

of the individual ocular muscles as a tubular sheath (*fascia musculares*). The sheath of the tendon of the obliquus superior is carried as far as the fibrous pulley of that muscle; the sheath of the obliquus inferior reaches as far as the floor of the orbit, to which it gives off a slip. The sheaths of the recti are gradually lost in the perimysium, but they give off important expansions. The expansion from the rectus superior blends with the tendon of the levator palpebrae; that of the rectus inferior is attached to the inferior tarsus. The expansions from the sheaths of the recti medialis and especially the rectus lateralis are strong and are attached to the lacrimal and zygomatic bones respectively. As they probably check the actions of the two recti, these structures have been named the **medial** and **lateral check ligaments**. A thickening of the lower part of the fascia bulbi, named the **suspensory ligament of the eye**, is slung like a hammock below the eyeball, and is expanded in the center and narrow at the ends, and attached to the zygomatic and lacrimal bones respectively.

The **periorbita** is the name given to the periosteum of the orbit. It is loosely connected to the bones and can be readily separated from them. It is continuous with the dura mater by processes that pass through the optic foramen and superior orbital fissure and with the sheath of the optic nerve. At the margin of the orbit, a process from the periorbita assists in forming the **orbital septum**. The periorbita has two other processes: one to enclose the lacrimal gland, the other to hold the pulley of the obliquus superior in position.

The **orbital septum** (*palpebral ligament*) (Fig. 13-32) is a membranous sheet that is continuous with the part of the periorbita that is attached to the edge of the orbit. In the upper eyelid, the orbital septum blends by its peripheral circumference with the tendon of the levator palpebrae superioris and the superior tarsus; in the lower eyelid, the orbital septum blends with the inferior tarsus. Medially it is thin, and after separating from the medial palpebral ligament, it is fixed to the lacrimal bone immediately behind the lacrimal sac. The septum is perforated by the vessels and nerves that pass from the orbital cavity to the face and scalp. The eyelids are richly supplied with blood.

## **Eyebrows**

The eyebrows (*supercilia*) are two arched eminences that surmount the superior margins of the orbits. The eyebrows consist of thickened integument that is connected beneath with the orbicularis oculi, corrugator, and frontalis muscles. They support numerous short, thick hairs.

## **Eyelids**

The eyelids (*palpebrae*) are two thin, movable covers placed in front of the eye that protect it from injury by their closure. The upper eyelid is larger and more movable than the lower, and is furnished with an elevator muscle, the levator palpebrae superioris. When the eyelids are open, an elliptical space, the **palpebral fissure** (*rima palpebrarum*), is left between their margins, the angles of which correspond to the junctions of the upper and lower eyelids. These angles are called the **palpebral commissures** or **canthi**.

The **lateral palpebral commissure** (*external or lateral canthus*) is more acute than the medial commissure, and the eyelids here lie in close contact with the bulb of the eye. The **medial palpebral commissure** (*internal or medial canthus*) is prolonged for a short distance toward the nose, and the two eyelids are separated by a triangular space, the **lacus lacrimalis** (Fig. 13-37). At the basal angles of the lacus lacrimalis, on the margin of each eyelid, is a small conical elevation, the **lacrimal papilla**, the apex of which is pierced by a small orifice, the **punctum lacrimale**. This opening is the commencement of the lacrimal duct.

**STRUCTURE OF THE EYELIDS.** (Fig. 13-33). The eyelids are composed of the following structures, from outer to inner surfaces: integument, areolar tissue, fibers of the orbicularis oculi, tarsus, orbital septum, tarsal glands, and conjunctiva. The upper eyelid, in addition, has the aponeurosis of the levator palpebrae superioris (Fig. 13-34).

The **integument** is extremely thin and continuous at the margins of the eyelids with the conjunctiva.

The **subcutaneous areolar tissue** is lax, delicate, and seldom contains any fat.

The **palpebral fibers of the orbicularis oculi** are thin, pale, and have an involuntary as well as a voluntary action.

**Fig. 13-33.** Sagittal section through the upper eyelid. (After Waldeyer.) *a*, Skin. *b*, Orbicularis oculi. *b'*, Marginal fasciculus of orbicularis (ciliary bundle). *c*, Levator palpebrae. *d*, Conjunctiva. *e*, Tarsus. *f*, Tarsal gland. *g*, Ciliary gland. *h*, Eyelashes. *i*, Small hairs of skin. *j*, Sweat glands. *k*, Posterior tarsal glands.

The **tarsi (tarsal plates)** (Fig. 13-34) are two thin, elongated plates of dense connective tissue about 2.5 cm long; one is placed in each eyelid and contributes to its form and support. The **superior tarsus**, the larger, is semilunar, about 10 mm in breadth at the center, and gradually narrows toward its extremities. To the anterior surface of this plate the aponeurosis of the levator palpebrae superioris is attached. The **inferior tarsus**, the smaller plate, is thin, elliptical, and has a vertical diameter of about 5 mm. The free or ciliary margins of these plates are thick and straight. The attached or orbital margins are connected to the circumference of the orbit by the orbital septum. The lateral angles are attached to the zygomatic bone by the lateral palpebral raphe. The medial angles of the two plates end at the lacus lacrimalis and are attached to the frontal process of the maxilla by the medial palpebral ligament.

**EYELASHES.** The eyelashes (*cilia*) are attached to the free edges of the eyelids; they are short, thick, curved hairs, arranged in a double or triple row: those of the upper eyelid, more numerous and longer than those of the lower, curve upward; those of the lower eyelid curve downward, so that they do not interlace when the lids are closed. Near the attachment of the eyelashes are the openings of the **ciliary glands**, which are arranged in several rows close to the free margin of the lid. These are regarded as enlarged and modified sudoriferous glands.

**Fig. 13-34.** The tarsi and their ligaments. Right eye; anterior view.

**TARSAL GLANDS.** The tarsal glands (Meibomian<sup>1</sup> glands) (Figs. 13-35; 13-36) are situated on the inner surfaces of the eyelids between the tarsi and conjunctiva. They may be seen distinctly through the conjunctiva when the eyelids are everted, having an appearance similar to parallel strings of pearls. There are about 30 glands in the upper eyelid and somewhat fewer in the lower. They are embedded in grooves in the inner surfaces of the tarsi and correspond in length with the breadth of these plates; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margins of the lids by minute apertures.

**STRUCTURE OF THE TARSAL GLANDS.** The tarsal glands are modified sebaceous glands; each consists of a single straight tube or follicle with numerous small lateral diverticula. The tubes are supported by a basement membrane and are lined at their mouths by stratified epithelium; the deeper parts of the tubes and the lateral offshoots are lined by a layer of polyhedral cells.

### Conjunctiva

The conjunctiva is the mucous membrane of the eye. It lines the inner surfaces of the eyelids or palpebrae and is reflected over the anterior part of the sclera.

The **palpebral portion** (*tunica conjunctiva palpebrarum*) is thick, opaque, highly vascular, and covered with numerous papillae; the deeper part has a considerable amount of

<sup>1</sup>Heinrich Meibom (1638–1700): A German physician and anatomist (Helmstadt).

**Fig. 13-36.** Anterior view of left eye with eyelids separated to show medial canthus.

lymphoid tissue. At the margins of the lids, the conjunctiva becomes continuous with the lining membrane of the ducts of the tarsal glands; through the lacrimal ducts, it is continuous with the lining membrane of the lacrimal sac and nasolacrimal duct. At the lateral angle of the upper eyelid, the ducts of the lacrimal gland open on the free surface of the conjunctiva, and at the medial angle it forms a semilunar fold, the **plica semilunaris** (Fig. 13-36). The line of reflection of the conjunctiva from the upper eyelid onto the bulb of the eye is named the **superior fornix**, and that from the lower lid is named the **inferior fornix**.

The **bulbar portion** (*tunica conjunctiva bulbi*) of the conjunctiva is loosely connected over the sclera; it is thin, transparent, destitute of papillae, and only slightly vascular. At the circumference of the cornea, the conjunctiva becomes the epithelium of the cornea, already described (see p. 1295). Lymphatics arise in the conjunctiva in a delicate zone around the cornea; these vessels run to the scleral conjunctiva. Lymphoid follicles are found in the conjunctiva, chiefly near the medial palpebral commissure. They were first described by Bruch<sup>1</sup>, in his description of Peyer's patches<sup>2</sup> of the small intestine, as "identical structures existing in the under eyelid of the ox."

<sup>1</sup>Carl Wilhelm Ludwig Bruch (1819–1884): A German anatomist (Basel and Giessen).

<sup>2</sup>Johann Conrad Peyer (1653–1712): Swiss anatomist and logician (Schaffhausen).

**Fig. 13-35.** The tarsal glands seen from the inner surface of the eyelids.

In and near the fornices, but more plentiful in the upper than in the lower eyelid, several convoluted tubular glands open on the surface of the conjunctiva.

**CARUNCULA LACRIMALIS.** The caruncula lacrimalis is a small, reddish protuberance situated at the medial palpebral commissure and filling up the lacus lacrimalis. It consists of a small island of skin containing sebaceous and sudoriferous glands, and it is the source of the whitish secretion that constantly collects in this region. A few slender hairs are attached to its surface. Lateral to the caruncula is a slight semilunar fold of conjunctiva, the concavity of which is directed toward the cornea; this is called the **plica semilunaris**. Smooth muscular fibers have been found in this fold, and in some of the domesticated animals it contains a thin plate of cartilage.

**NERVES.** The **nerves** in the conjunctiva are numerous and form rich plexuses. They appear to terminate in a peculiar form of tactile corpuscle called terminal bulbs.

### Lacrimal Apparatus

The lacrimal apparatus (Fig. 13-37) consists of (a) the **lacrimal gland**, which secretes the tears, and its excretory ducts, which convey the fluid to the surface of the eye; and (b) the **lacrimal ducts**, the **lacrimal sac**, and the **nasolacrimal duct**, by which the fluid is conveyed into the cavity of the nose.

**LACRIMAL GLAND.** The lacrimal gland (Figs. 13-34; 13-35) is superior and lateral to the bulb and is lodged in the lacrimal fossa on the medial side of the zygomatic process of the frontal bone. It is oval, about the size and shape of an almond, and consists of two portions. The **orbital part** (*pars orbitalis*; *superior lacrimal gland*) is connected to the periosteum of the orbit by a few fibrous bands and rests upon the tendons of the recti superioris and lateralis, which separate it from the bulb of the eye. The **palpebral part** (*pars palpebralis*; *inferior lacrimal gland*) is separated from the orbital part by a fibrous septum and projects into the back part of the upper eyelid, where its deep surface is related to the conjunctiva. The ducts of the

**FIG. 13-37.** Topography of the lacrimal apparatus. The lacrimal and tarsal glands are shown in blue. The nose and a portion of the face have been cut away. (Eycleshymer and Jones.)

glands, numbering six to twelve, run obliquely beneath the conjunctiva for a short distance and open along the upper and lateral half of the superior conjunctival fornix.

**LACRIMAL DUCTS.** The lacrimal ducts (*lacrimal canals*), one in each eyelid, commence at minute orifices, termed **puncta lacrimalia**, on the summits of the **papillae lacrimales**, which are on the margins of the lids at the lateral extremity of the *lacus lacrimalis*. The **superior duct**, the smaller and shorter of the two, at first ascends and then bends at an acute angle and passes medialward and downward to the lacrimal sac. The **inferior duct** at first descends and then runs almost horizontally to the lacrimal sac. At the angles they are dilated into **ampullae**; their walls are dense, and their mucous lining is covered by stratified squamous epithelium placed on a basement membrane. Outside the basement membrane is a layer of striped muscle that is continuous with the lacrimal part of the *orbicularis oculi*; at the base of each lacrimal papilla the muscular fibers are circularly arranged and form a kind of sphincter.

**LACRIMAL SAC.** The lacrimal sac is the upper dilated end of the nasolacrimal duct. It is lodged in a deep groove formed by the lacrimal bone and the frontal process of the maxilla. It is oval and measures 12 to 15 mm long; its upper end is closed and round, and its lower end continues into the nasolacrimal duct. The superficial surface of the lacrimal sac is covered by a fibrous expansion derived from the medial palpebral ligament, and its deep surface is crossed by the lacrimal part of the *orbicularis oculi* (p. 441), which is attached to the crest on the lacrimal bone.

**NASOLACRIMAL DUCT.** The nasolacrimal duct (*nasal duct*) is a membranous canal, about 18 mm long, that extends from the lower part of the lacrimal sac to the inferior meatus of the nose, where it ends in a somewhat expanded orifice that is provided with an imperfect valve, the **plica lacrimalis** (*Hasneri*<sup>1</sup>), which is formed by a fold of the mucous membrane. The nasolacrimal duct is contained in an osseous canal that is formed by the maxilla, the lacrimal bone, and the inferior nasal concha. It is narrower in the middle than at either end, and is directed downward, backward, and a little lateral-

ward. The mucous lining of the lacrimal sac and nasolacrimal duct is covered with columnar epithelium, which is ciliated in places.

**STRUCTURE OF THE LACRIMAL GLAND.** In structure and general appearance the lacrimal gland resembles the serous salivary glands.

**STRUCTURE OF THE LACRIMAL SAC.** The lacrimal sac consists of a fibrous elastic coat that is lined internally by mucous membrane. The mucous membrane is continuous through the lacrimal ducts with the conjunctiva, and through the nasolacrimal duct with the mucous membrane of the nasal cavity.

## Organ of Hearing and Equilibration: The Ear

The **ear** (*organum vestibulocochleare*; *organum oticum*; *organum stato-acousticum*), or **organ of hearing and equilibration**, is divisible into three parts: the **external ear**, the **middle ear** or **tympanic cavity**, and the **internal ear** or **labyrinth**.

### DEVELOPMENT

The first rudiment of the internal ear appears shortly after that of the eye in the form of a patch of thickened ectoderm, the **auditory plate**, over the region of the hindbrain. The auditory plate becomes depressed and converted into the **auditory pit** (Fig. 13-38). The mouth of the pit is then closed, and the **auditory vesicle** is formed (Fig. 13-39); from this the epithelial lining of the membranous labyrinth is derived. From the vesicle certain diverticula are given off that form the various parts of the membranous labyrinth (Figs.

**Fig. 13-38.** Section through the head of a human embryo, about 12 days old, in the region of the hindbrain. (Kollmann.)

<sup>1</sup>Joseph Ritter von Artha Hasner (1819-1892): A Bohemian ophthalmologist (Prague).

**Fig. 13-39.** Section through hindbrain and auditory vesicles of an embryo more advanced than that of Figure 13-38. (After His.)

13-40; 13-41). One from the middle part forms the ductus and saccus endolymphaticus; another from the anterior end gradually elongates, and forming a tube coiled on itself, becomes the cochlear duct, the vestibular extremity of which is subsequently constricted to form the canalis reuniens. Three other diverticula appear as disc-like evaginations on the surface of the vesicle. The central parts of the walls of the discs coalesce and disappear, while the peripheral portions persist to form the semicircular ducts; of these, the anterior is the first and the lateral is the last to be completed. The central part of the vesicle represents the membranous vestibule, and this is subdivided by a constriction into a smaller ventral part, the saccule, and a larger dorsal and posterior part, the utricle. This subdivision is effected by a fold that extends deeply into the proximal part of the ductus endolymphaticus, so that the utricle and saccule ultimately communicate with each other by means of a Y-shaped canal. The saccule opens into the cochlear duct through the canalis reuniens, and the semicircular ducts communicate with the utricle.

The mesodermal tissue surrounding the various parts of the epithelial labyrinth is converted into a cartilaginous capsule, and this is finally ossified to form the bony labyrinth. Between the cartilaginous capsule and the epithelial structures is a stratum of mesodermal tissue that is differentiated into three layers: an outer layer, which forms the periosteal lining of the bony labyrinth; an inner layer, which is in direct contact with the epithelial structures; and an intermediate layer, which consists of gelatinous tissue. The perilymphatic spaces are developed by the absorption of this gelatinous tissue. The modiolus and osseous spiral lamina of the cochlea are not preformed in cartilage but are ossified directly from connective tissue.

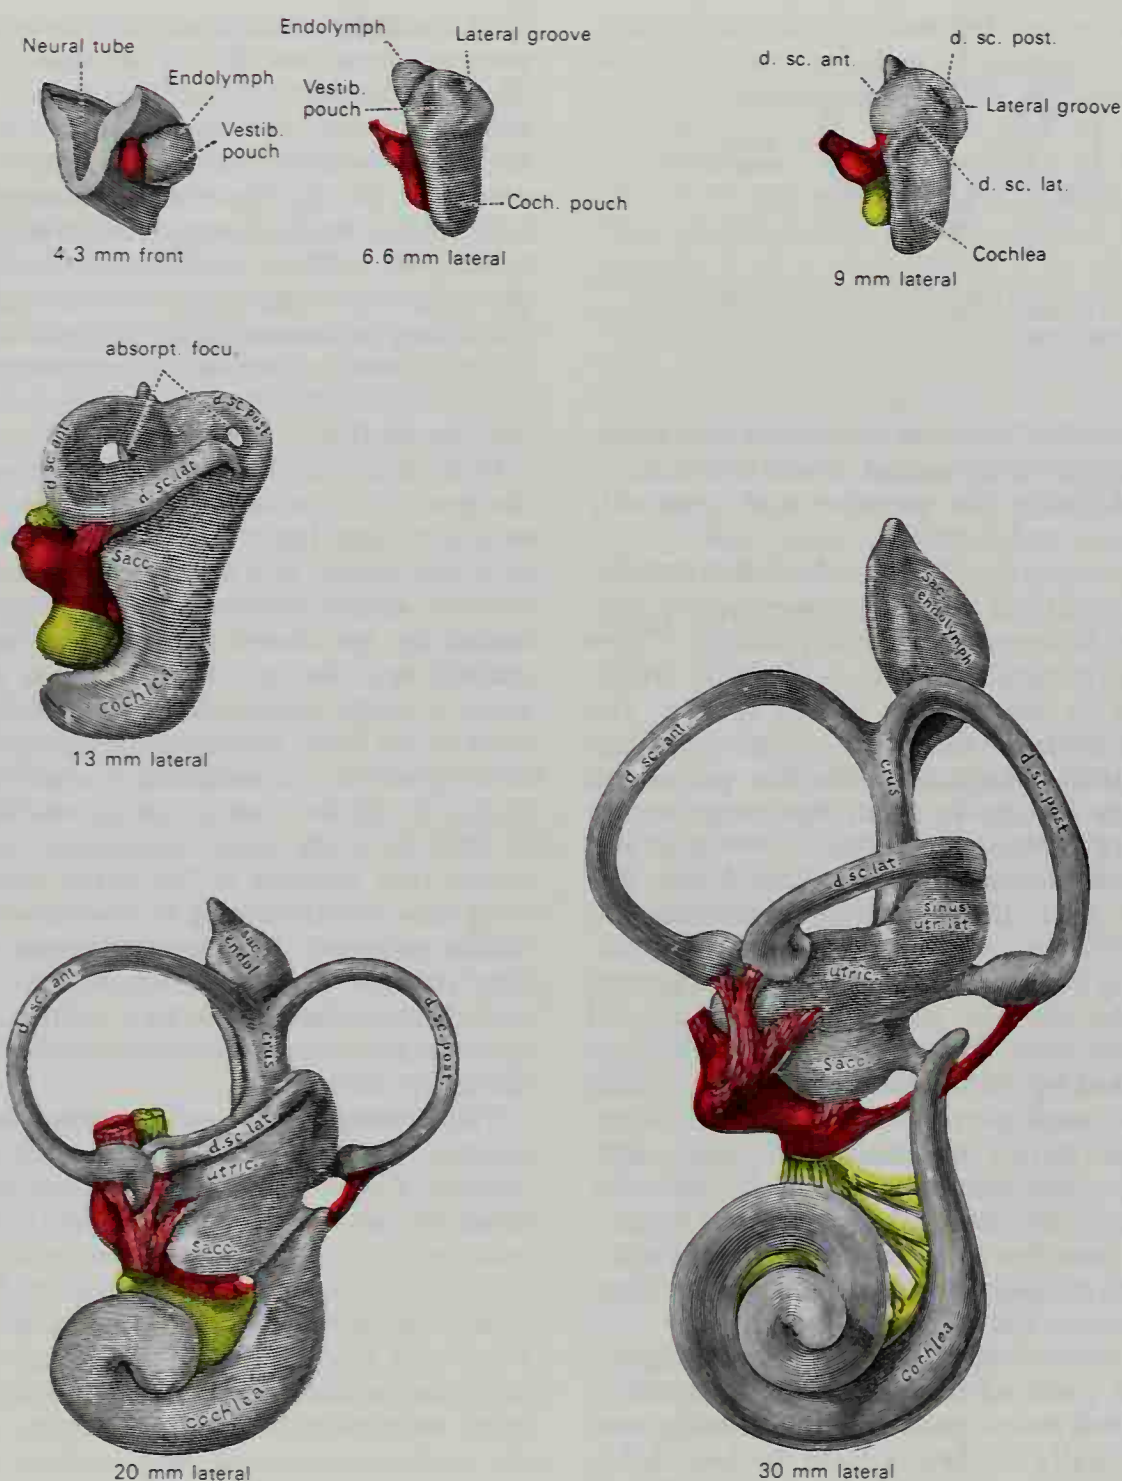

The **middle ear** and **auditory tube** are developed from the first pharyngeal pouch. The entodermal lining of the dorsal end of this pouch is in contact with the ectoderm of the corresponding pharyngeal groove; by the extension of the mesoderm between these two layers, the **tympanic membrane** forms. During the sixth or seventh month, the **tympanic antrum** appears as an upward and backward expansion of the tympanic cavity. There is some difference of opinion regarding the exact mode of development of the ossicles of the middle ear. The view generally held is that the **malleus** develops from the proximal end of the mandibular (Meckel's) cartilage (Fig. 2-48); the **incus** develops in the proximal end of the mandibular arch; and the **stapes** develops from the proximal end of the hyoid arch. The malleus, with the exception of its anterior process, is ossified from a single center that appears near the neck of the bone; the anterior process is ossified separately in membrane and joins the main part of the bone about the sixth month of fetal life. The incus is ossified from one center that appears in the upper part of its long crus and ultimately extends into its lenticular process. The stapes first appears as a ring (*anulus stapedius*) encircling a small vessel, the stapedial artery, which subsequently atrophies; it is ossified from a single center in its base.

The **external ear** and **external acoustic meatus** develop from the first branchial groove. The lower part of this groove extends inward as a funnel-shaped tube (primary meatus), from which the cartilaginous portion and a small part of the roof of the osseous portion of the meatus are developed. From the lower part of the funnel-shaped tube, an epithelial lamina extends downward and inward along the inferior wall of the primitive tympanic cavity; by the splitting of this lamina the inner part of the meatus (secondary meatus) is produced, while the inner portion of the lamina forms the cutaneous stratum of the tympanic membrane.

The **auricula** or **pinna** develops by the gradual differentiation or tubercles that appear around the margin of the first branchial groove (see Chapter 2 and Fig. 2-57).

The **acoustic nerve** rudiment appears about the end of the third week as a group of ganglion cells closely applied to the cranial edge of the auditory vesicle. Whether these cells are derived from the ectoderm adjoin-

ing the auditory vesicle or whether they have migrated from the wall of the neural tube is not yet certain. The ganglion gradually splits into two parts: the **vestibular ganglion** and the **spiral ganglion**. The peripheral branches of the vestibular ganglion pass in two divisions: the pars superior gives rami to

the superior ampulla of the anterior semicircular duct, to the lateral ampulla, and to the utricle; the pars inferior gives rami to the saccule and the posterior ampulla. The proximal fibers of the vestibular ganglion form the vestibular nerve; the proximal fibers of the spiral ganglion form the cochlear nerve.

FIG. 13-41. Median views of membranous labyrinth and acoustic complex in human embryos. 25 × dia. (Streeter.)

## EXTERNAL EAR

The **external ear** consists of the expanded portion named the **auricula** or **pinna** and the **external acoustic meatus**. The former projects from the side of the head and collects the vibrations of the air by which sound is produced; the latter leads inward from the bottom of the auricula and conducts the vibrations to the tympanic cavity.

## Auricula

The **auricula** or **pinna** (Fig. 13-42) is ovoid, with its larger end directed upward. Its lateral surface is irregularly concave, directed slightly anteriorly, and has numerous eminences and depressions, to which names have been assigned. The prominent rim of the auricula is called the **helix**. Where the helix turns inferiorly, a small tubercle, the **auricu-**

FIG. 13-42. The auricula, lateral surface.

lar tubercle of Darwin, is frequently seen; this tubercle is evident about the sixth month of fetal life, when the whole auricula closely resembles that of some adult monkeys. Another curved prominence, parallel with and anterior to the helix, is called the **antihelix**; this divides above into two crura, between which is a triangular depression, the **fossa triangularis**. The narrow curved depression between the helix and the antihelix is called the **scapha**. The antihelix describes a curve around a deep, capacious cavity, the **concha**, which is partially divided into two parts by the **crus** or commencement of the helix; the superior part is termed the **cymba conchae**, and the inferior part is called the **cavum conchae**. Anterior to the concha and projecting posteriorly over the meatus is a small pointed eminence, the **tragus**, so called because it is generally covered on its undersurface with a tuft of hair resembling a goat's beard. Opposite the tragus and separated from it by the **intertragic notch** is a small tubercle, the **antitragus**. Below this is the **lobule**, which is composed of areolar and adipose tissues and lacks the firmness and elasticity of the rest of the auricula.

The cranial surface of the auricula presents elevations that correspond to the depressions on its lateral surface, after which they are named, e.g., **eminentia conchae**, **eminentia triangularis**.

#### STRUCTURE OF THE AURICULA

The auricula is composed of a thin plate of yellow elastic cartilage covered with integument; it is connected to the surrounding

parts by ligaments and muscles and to the commencement of the external acoustic meatus by fibrous tissue.

**INTEGUMENT.** The **skin** is thin, closely adherent to the cartilage, and covered with fine hairs furnished with sebaceous glands, which are most numerous in the concha and scaphoid fossa. On the tragus and antitragus, the hairs are strong and numerous. The skin of the auricula is continuous with that lining the external acoustic meatus.

**CARTILAGE.** The cartilage of the auricula (*cartilago auriculæ*; cartilage of the pinna) (Figs. 13-42; 13-43) consists of a single piece; it gives form to this part of the ear, and upon its surface are found the eminences and depressions just described. It is absent from the lobule; it is also deficient between the tragus and beginning of the helix, the gap being filled by dense fibrous tissue. At the front of the auricula, where the helix bends upward, is a small projection of cartilage called the **spina helicis**; in the lower part of the helix, the cartilage is prolonged downward as a tail-like process, the **cauda helicis**; this is separated from the antihelix by a fissure, the **fissura antitragohelicina**. The cranial aspect of the cartilage exhibits a transverse furrow, the **sulcus antihelicis transversus**, which corresponds with the inferior crus of the antihelix and separates the **eminentia conchae** from the **eminentia triangularis**. The **eminentia conchae** is crossed by a vertical ridge (**ponticulus**), which gives attachment to the auricularis posterior muscle. In the cartilage of the auricula are two fissures, one behind the crus helicis and another in the tragus.

FIG. 13-43. Cranial surface of cartilage of right auricula.

**LIGAMENTS.** The ligaments of the auricula (*ligamenta auricularia* [Valsalva<sup>1</sup>]; *ligaments of the pinna*) consist of two sets: (1) **extrinsic**, connecting the auricula to the side of the head; (2) **intrinsic**, connecting various parts of the cartilage together.

The **extrinsic ligaments** are two, anterior and posterior. The *anterior ligament* extends from the tragus and *spina helix* to the root of the zygomatic process of the temporal bone. The *posterior ligament* passes from the posterior surface of the concha to the outer surface of the mastoid process.

The chief **intrinsic ligaments** are: (1) a strong fibrous band that stretches from the tragus to the commencement of the helix, completing the meatus in front and partly encircling the boundary of the concha; and (2) a band between the antihelix and the cauda helix. Other less important bands are found on the cranial surface of the pinna.

**MUSCLES.** The muscles of the auricula (Fig. 13-44) consist of two sets: (1) **extrinsic**, which connect the auricula with the skull and scalp and move it as a whole; and (2) **intrinsic**, which extend from one part of the auricle to another.

<sup>1</sup>Antonio Maria Valsalva (1666-1723): An Italian anatomist (Bologna).

FIG. 13-44. The muscles of the auricula.

The **extrinsic muscles** are the *auriculares anterior, superior, and posterior*, described with the facial muscles in Chapter 6.

The **intrinsic muscles** are:

Helicis major  
Helicis minor  
Tragicus  
Antitragicus  
Transversus auriculæ  
Obliquus auriculæ

The **helicis major** is a narrow vertical band situated upon the anterior margin of the helix. It arises from the *spina helix* and is inserted into the anterior border of the helix, where the helix is about to curve backward.

The **helicis minor** is an oblique fasciculus that covers the *crus helicis*.

The **tragicus** is a short, flat vertical band on the lateral surface of the tragus.

The **antitragicus** arises from the outer part of the antitragus and is inserted into the cauda helix and antihelix.

The **transversus auriculæ** is placed on the cranial surface of the pinna. It consists of scattered fibers, partly tendinous and partly muscular, that extend from the *eminencia conchæ* to the prominence corresponding with the scapha.

The **obliquus auriculæ**, also on the cranial surface, consists of a few fibers that extend from the upper and back part of the concha to the convexity immediately above it.

**VESSELS.** The **arteries** of the auricula are the posterior auricular from the external carotid, the anterior auricular from the superficial temporal, and a branch from the occipital artery.

The **veins** accompany the corresponding arteries.

**NERVES.** The *auriculares anterior and superior* and the *intrinsic muscles* on the lateral surface are supplied by the temporal branch of the facial nerve. The *auricularis posterior* and the *intrinsic muscles* on the cranial surface are supplied by the posterior auricular branch of the same nerve.

The **sensory nerves** are: the great auricular, from the cervical plexus; the auricular branch of the vagus; the auriculotemporal branch of the mandibular nerve; and the lesser occipital from the cervical plexus.

### External Acoustic Meatus

The **external acoustic meatus** (*external auditory canal or meatus*) extends from the bottom of the concha to the tympanic mem-

**FIG. 13-45.** External and middle ear, opened anteriorly; right side.

brane (Figs. 13-45; 13-46). It is about 4 cm long if measured from the tragus; from the bottom of the concha it is about 2.5 cm long. It forms an S-shaped curve, and is directed at first inward, forward, and slightly upward (*pars externa*); it then passes inward and backward (*pars media*), and lastly is carried

inward, forward, and slightly downward (*pars interna*). It is an oval cylindrical canal, the greatest diameter being directed downward and backward at the external orifice, but nearly horizontal at the inner end. It has two constrictions, one near the inner end of the cartilaginous portion, and another, the

**FIG. 13-46.** Horizontal section through left ear; upper half of section.

**isthmus**, in the osseous portion about 2 cm from the bottom of the concha. The tympanic membrane, which closes the inner end of the meatus, is directed obliquely, so the floor and anterior wall of the meatus are longer than the roof and posterior wall.

The external acoustic meatus is formed partly by cartilage and membrane and partly by bone, and it is lined with skin.

The **cartilaginous portion** is about 8 mm long; it is continuous with the cartilage of the auricula and firmly attached to the circumference of the auditory process of the temporal bone. The cartilage is deficient at the cranial and posterior part of the meatus, where it is replaced by fibrous membrane; two or three deep fissures are present in the anterior part of the cartilage.

The **osseous portion** is about 16 mm long and is narrower than the cartilaginous portion. It is directed inward and a little forward, forming in its course a slight curve, the convexity of which is upward and backward. The inner end is smaller than the outer end and is sloped; the anterior wall projects beyond the posterior for about 4 mm. This end is marked, except at its cranial part, by a narrow groove, the **tympanic sulcus**, in which the circumference of the tympanic membrane is attached. Its outer end is dilated and rough in the greater part of its circumference for the attachment of the cartilage of the auricula. The anterior and inferior parts of the osseous portion are formed by a curved plate of bone—the tympanic part of the temporal bone—which in the fetus exists as a separate ring (**anulus tympanicus**) that is incomplete at its cranial part (Chapter 4).

The **skin** lining the meatus is very thin; it adheres closely to the cartilaginous and osseous portions of the tube and covers the outer surface of the tympanic membrane. After maceration, the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands that secrete the ear wax; their structure resembles that of the sudoriferous glands.

**RELATIONS OF THE MEATUS.** Anterior to the osseous part is the condyle of the mandible, but the latter is frequently separated from the cartilaginous part by a portion of the parotid gland. The movements of the jaw influence to some extent the lumen of this

latter portion. Posterior to the osseous part are the mastoid air cells, which are separated from the meatus by a thin layer of bone.

**VESSELS.** The **arteries** supplying the walls of the meatus are branches from the posterior auricular, maxillary, and superficial temporal arteries.

**NERVES.** The **nerves** are chiefly derived from the auriculotemporal branch of the mandibular nerve and the auricular branch of the vagus.

## MIDDLE EAR OR TYMPANUM

The **middle ear** or **tympanic cavity** (*drum; tympanum*) is an irregular, laterally compressed space within the temporal bone. It is filled with air, which is conveyed to it from the nasal part of the pharynx through the auditory tube. The cavity contains a chain of tiny movable bones that bridge from its lateral to its medial wall and convey the vibrations communicated to the tympanic membrane across the cavity to the internal ear.

The tympanic cavity consists of two parts: the **tympanic cavity proper**, opposite the tympanic membrane, and the **attic** or **epitympanic recess**, cranial to the level of the membrane which contains the upper half of the malleus and the greater part of the incus. Including the attic, the vertical and anteroposterior diameters of the cavity are each about 15 mm. The transverse diameter measures about 6 mm superiorly and 4 mm inferiorly; opposite the center of the tympanic membrane it is only about 2 mm. The tympanic cavity is bounded laterally by the tympanic membrane; medially, by the lateral wall of the internal ear. It communicates posteriorly with the tympanic antrum and through it with the mastoid air cells; anteriorly, the tympanic cavity communicates with the auditory tube (Fig. 13-45).

### Tegmental Wall or Roof

The **roof** is formed by a thin plate of bone, the **tegmen tympani**, which separates the tympanic from the cranial cavity. It is situated on the anterior surface of the petrous portion of the temporal bone close to its angle of junction with the squama temporalis. It is prolonged posteriorly to roof in the tympanic antrum, and anteriorly to cover the semicanal for the tensor tympani muscle. Its lateral edge corresponds with the remains of the petrosquamous suture.

### Jugular Wall or Floor

The **floor** is narrow and consists of a thin plate of bone (**fundus tympani**), which separates the tympanic cavity from the jugular fossa. It has, near the labyrinthine wall, a small aperture for the passage of the tympanic branch of the glossopharyngeal nerve.

### Membranous or Lateral Wall

The **lateral wall** (outer wall) is formed mainly by the tympanic membrane and partly by the ring of bone into which this membrane is inserted. The ring of bone is incomplete at its upper part, forming a notch (of Rivinus<sup>1</sup>), close to which are three small apertures: the **iter chordae posterius**, the **petrotympanic fissure**, and the **iter chordae anterior**.

The **iter chordae posterius** (*apertura tympanica canaliculi chordae*) is situated in the angle of junction between the mastoid and membranous wall of the tympanic cavity,

<sup>1</sup>Augustus Quirinus Rivinus (1652–1723): A German anatomist and botanist (Leipzig).

immediately posterior to the tympanic membrane and on a level with the superior end of the manubrium of the malleus. It leads into a minute canal in the mastoid bone that descends almost parallel with the facial nerve and meets the facial canal at an acute angle near the stylomastoid foramen. Through it the chorda tympani nerve enters the tympanic cavity (Fig. 13-47).

The **petrotympanic fissure** (Glaserian fissure<sup>2</sup>) (Fig. 13-47) opens just superior and anterior to the ring of bone into which the tympanic membrane is inserted; in this situation it is a mere slit about 2 mm long. It lodges the anterior process and anterior ligament of the malleus and gives passage to the anterior tympanic branch of the maxillary artery.

The **iter chordae anterior** (*canal of Huguier*<sup>3</sup>) is at the medial end of the petrotympanic fissure; through it the chorda tympani nerve leaves the tympanic cavity.

<sup>2</sup>Johann Heinrich Glaser (1629–1675): A Swiss anatomist (Basel).

<sup>3</sup>Pierre Charles Huguier (1804–1874): A French surgeon (Paris).

**Fig. 13-47.** The right membrana tympani with the malleus and the chorda tympani, viewed from within. (Spalteholz.)

### Tympanic Membrane

The **tympanic membrane** (Figs. 13-47; 13-48) separates the tympanic cavity from the bottom of the external acoustic meatus. It is a thin, semitransparent membrane, nearly oval, directed very obliquely inferiorly and medially to form an angle of about  $55^\circ$  with the floor of the meatus. Its longest diameter, almost vertical, measures 9 to 10 mm; its shortest diameter measures 8 to 9 mm. The greater part of its circumference is thick and forms a **fibrocartilaginous ring**, which is fixed in the **tympanic sulcus** at the inner end of the meatus. This sulcus is deficient superiorly at the **notch of Rivinus**, and from the ends of this notch two bands, the **anterior** and **posterior malleolar folds**, are prolonged to the lateral process of the malleus. The small, somewhat triangular part of the membrane situated superior to these folds is lax

and thin and is named the **pars flaccida**, as opposed to the rest of the membrane, which is called the **pars tensa**. The manubrium of the malleus is firmly attached to the medial surface of the membrane as far as its center, which it draws inward toward the tympanic cavity. The lateral surface of the membrane is thus concave, and the most depressed part of this concavity is named the **umbo**.

### STRUCTURE OF THE TYMPANIC MEMBRANE

The tympanic membrane is composed of three strata: **lateral** (cutaneous), **intermediate** (fibrous), and **medial** (mucous). The **cutaneous stratum** is derived from the integument lining the meatus. The **fibrous stratum** consists of two layers: a **radiate stratum**, the fibers of which diverge from the manubrium of the malleus, and a **circular stratum**, the fibers of which are plentiful around the cir-

**Fig. 13-48.** The lateral aspect of the right tympanic membrane as seen through an otoscope. The membrane is oval and measures about 11 mm in its long diameter and about 9 mm across. (Redrawn after Sobotta.)

cumference but sparse and scattered near the center of the membrane. Branched or dendritic fibers are also present, especially in the posterior half of the membrane. The **mucous stratum** is the internal surface of the membrane derived from the lining of the cavity.

**VESSELS AND NERVES.** The **arteries** of the tympanic membrane are derived from the deep auricular branch of the maxillary artery, which ramifies beneath the cutaneous stratum, and from the stylo-mastoid branch of the posterior auricular artery and the tympanic branch of the maxillary artery, which are distributed on the mucous surface. The superficial veins open into the external jugular; those on the deep surface drain partly into the transverse sinus and veins of the dura mater, and partly into a plexus on the auditory tube.

The membrane receives its chief **nerve supply** from the auriculotemporal branch of the mandibular nerve; the auricular branch of the vagus and the tympanic branch of the glossopharyngeal nerve also supply it.

### **Labyrinthic or Medial Wall**

The **medial wall** (inner wall) is directed vertically and presents for examination the **fenestrae vestibuli** and **cochleae**, the **prom-**

**ontory**, and the **prominence of the facial canal** (Fig. 13-49).

The **fenestra vestibuli** (*fenestra ovalis*; oval window) is a reniform opening leading from the tympanic cavity into the vestibule of the internal ear. Its long diameter is horizontal, and its convex border is upward. In the intact body it is occupied by the base of the stapes, the circumference of which is secured by the annular ligament to the margin of the foramen (Fig. 13-50).

The **fenestra cochleae** (*fenestra rotunda*; round window) is situated inferior and a little posterior to the fenestra vestibuli, from which it is separated by a rounded elevation, the **promontory**. It is placed at the bottom of a funnel-shaped depression and, in the macerated bone, leads into the cochlea of the internal ear; in the intact body it is closed by a membrane, the **secondary tympanic membrane**, which is concave toward the cochlea. This membrane consists of three layers: an external or mucous layer derived from the mucous lining of the tympanic cavity; an internal layer from the lining membrane of the cochlea; and an intermediate or fibrous layer.

The **promontory** (*promontorium*) is a rounded prominence formed by the outward

**FIG. 13-49.** Coronal section of right temporal bone.

**Fig. 13-50.** The medial wall and part of the posterior and anterior walls of the right tympanic cavity, lateral view. (Spalteholz.) (See Fig. 13-49.)

projection of the first turn of the cochlea. It is placed between the fenestrae, and its surface is furrowed by small grooves for the nerves of the tympanic plexus. A minute spicule of bone frequently connects the promontory to the pyramidal eminence.

The **prominence of the facial canal** (*prominentia canalis facialis*; *prominence of aqueduct of Fallopius*<sup>1</sup>) indicates the position of the bony canal in which the facial nerve is contained; this canal traverses the labyrinthine wall of the tympanic cavity superior to the fenestra vestibuli, and posterior to that opening, curves nearly vertically inferiorly along the mastoid wall (Fig. 13-51).

### **Mastoid or Posterior Wall**

The **posterior wall** presents for examination the **entrance to the tympanic antrum**, the **pyramidal eminence**, and the **fossa incudis**.

The **entrance to the antrum** is a large, ir-

regular aperture that leads posteriorly from the epitympanic recess into a considerable air space, the **tympanic or mastoid antrum** (see Chapter 4). The antrum leads posteriorly and inferiorly into the **mastoid air cells**, which vary greatly in number, size, and form. The antrum and mastoid air cells are lined by mucous membrane that is continuous with that which lines the tympanic cavity. On the medial wall of the entrance to the antrum is a rounded eminence, situated superior and posterior to the prominence of the facial canal; it corresponds with the position of the ampullated ends of the anterior and lateral semicircular canals.

The **pyramidal eminence** (*pyramid*) is situated immediately posterior to the fenestra vestibuli and anterior to the vertical portion of the facial canal. It is hollow but contains the stapedius muscle. Its summit projects anteriorly toward the fenestra vestibuli and is pierced by a small aperture that transmits the tendon of the muscle. The cavity in the pyramidal eminence is prolonged posteriorly toward the facial canal and communicates with it by a minute aperture that trans-

<sup>1</sup>Gabriele Falloppio (1523-1563): An Italian anatomist and surgeon (Padua).

**Fig. 13-51.** View of the medial wall of the tympanum (enlarged). (See Fig. 13-49.)

mits a branch of the facial nerve to the stapedius muscle.

The **fossa incudis** is a small depression in the inferior and posterior part of the epitympanic recess; it lodges the short crus of the incus.

### **Carotid or Anterior Wall**

The **anterior wall** corresponds with the carotid canal, from which it is separated by a thin plate of bone that is perforated by the tympanic branch of the internal carotid artery and the caroticotympanic nerve, which connects the sympathetic plexus on the internal carotid artery with the tympanic plexus on the promontory. At the superior part of the anterior wall are the orifice of the semicanal for the tensor tympani muscle and the tympanic orifice of the auditory tube, separated from each other by a thin horizontal plate of bone, the **septum canalis musculotubarii**. These canals run from the tympanic cavity medialward to the retiring angle between the squama and the petrous portion of the temporal bone.

The **semicanal for the tensor tympani** (*semicanalis m. tensoris tympani*) is the superior and the smaller of the two canals; it is cylindrical and lies beneath the tegmen tympani. It extends to the labyrinthine wall of the tympanic cavity and ends immediately above the fenestra vestibuli. The **septum canalis musculotubarii** (*processus cochleariformis*) passes posteriorly, forming its lateral wall and floor; it expands above the anterior end of the fenestra vestibuli and terminates there by curving laterally to form a pulley over which the tendon of the muscle passes.

### **Auditory Tube**

The **auditory tube** (*tuba auditiva*; *Eustachian tube*<sup>1</sup>) is the channel through which the tympanic cavity communicates with the nasal part of the pharynx. Its length is about 36 mm, and in its medialward course it forms an angle of about 45° with the sagittal plane and an angle of 30 to 40° with the horizontal plane. Its walls are composed partly of bone and partly of cartilage and fibrous tissue (Fig. 13-45).

The **osseous portion** is about 12 mm long. It begins in the carotid wall of the tympanic cavity, inferior to the septum canalis musculotubarii, and gradually narrowing, ends at the angle of junction of the squama and the petrous portion of the temporal bone. Its extremity has a jagged margin that serves for the attachment of the cartilaginous portion.

The **cartilaginous portion**, about 24 mm long, is contained in a triangular plate of elastic fibrocartilage, the apex of which is attached to the margin of the medial end of the osseous portion of the tube, while the base lies directly under the mucous membrane of the nasal part of the pharynx, where it forms an elevation, the **torus tubarius** or cushion, posterior to the pharyngeal orifice of the tube. The superior edge of the cartilage is bent over laterally, forming a groove or furrow that is open inferiorly and laterally. The part of the canal lying in this furrow is completed by fibrous membrane. The cartilage lies in a groove between the petrous part of the temporal and the great

<sup>1</sup>Bartolommeo Eustachio (1520?-1574): An Italian anatomist (Rome).

wing of the sphenoid, and it ends opposite the middle of the medial pterygoid plate.

The cartilaginous and bony portions of the tube are not in the same plane, the former inclining inferiorly a little more than the latter. The diameter of the tube is not uniform throughout; it is greatest at the pharyngeal orifice, least at the junction of the bony and cartilaginous portions, and again increases toward the tympanic opening. The narrowest part of the tube is termed the **isthmus**. The position and relations of the **pharyngeal orifice** are described with the nasal part of the pharynx.

The mucous membrane of the tube is continuous with that of the nasal part of the pharynx and the tympanic cavity. It is covered with ciliated epithelium and is thin in the osseous portion, while in the cartilaginous portion it contains many mucous glands and, near the pharyngeal orifice, a considerable amount of adenoid tissue, the **tubal tonsil**. The tube is opened during deglutition by the salpingopharyngeus and dilatator tubae muscles. The latter arises from the hook of the cartilage and from the membranous part of the tube and blends below with the tensor veli palatini.

### Auditory Ossicles

The tympanic cavity contains a chain of three movable ossicles, the **malleus**, **incus**, and **stapes**. The first is attached to the tympanic membrane, the last to the circumference of the fenestra vestibuli, the incus being placed between and connected to both by delicate articulations (Fig. 13-55).

**MALLEUS.** The malleus (Fig. 13-52), so named from its fancied resemblance to a hammer, consists of a **head**, **neck**, and three

processes, viz., the **manubrium** and the **anterior** and **lateral processes**.

The **head** is the large superior extremity of the bone; it is oval and articulates posteriorly with the incus, being free in the rest of its extent. The facet for articulation with the incus is constricted near the middle and consists of a superior larger and an inferior smaller part, which are bent nearly at a right angle to each other. Opposite the constriction, the inferior margin of the facet projects in the form of a process, the **cog-tooth** or **spur of the malleus**.

The **neck** is the narrow contracted part joining the head with a prominence to which the anterior and posterior processes are attached.

The **manubrium mallei** is connected by its lateral margin with the tympanic membrane. It is directed slightly posteriorly as well as inferiorly; it decreases in size toward its free end, which is slightly curved and flattened transversely. On its medial side, near the head end, is a slight projection into which the tendon of the tensor tympani is inserted.

The **anterior process** is a delicate spicule directed anteriorly toward the petrotympanic fissure, to which it is connected by ligamentous fibers. In the fetus this is the longest process of the malleus, and it is directly continuous with the cartilage of Meckel.<sup>1</sup>

The **lateral process** is a slight conical projection that springs from the root of the manubrium. It is directed laterally and is attached to the superior part of the tympanic membrane and, by means of the anterior and posterior malleolar folds, to the extremities of the notch of Rivinus.

**INCUS.** The incus (Fig. 13-53) received its name from its resemblance to an anvil, but it looks more like a premolar tooth with two

Fig. 13-52. Left malleus. A, Posterior view. B, Medial view.

Fig. 13-53. Left incus. A, Medial view. B, Anterior view.

<sup>1</sup>Johann Friedrich Meckel (the Younger) (1781-1833): A German anatomist and surgeon (Halle).

roots that differ in length and are widely separated from each other. It consists of a **body** and **two crura**.

The **body** is somewhat cubical but compressed transversely. On its anterior surface is a deeply concavo-convex facet that articulates with the head of the malleus.

The two crura diverge from each other nearly at right angles. The **short crus**, which is somewhat conical, projects almost horizontally backward and is attached to the **fossa incudis** in the posterior part of the epitympanic recess. The **long crus** descends nearly vertically parallel to the manubrium of the malleus and, bending medialward, ends in a rounded projection, the **lenticular process**, which is tipped with cartilage and articulates with the head of the stapes.

**STAPES.** The stapes (Fig. 13-54), so called from its resemblance to a stirrup, consists of a **head**, **neck**, **two crura**, and a **base**.

The **head** has a depression, which is covered by cartilage; it articulates with the lenticular process of the incus.

The **neck**, the constricted part of the bone succeeding the head, has the insertion of the tendon of the stapedius muscle attached to it.

The **two crura** diverge from the neck and are connected at their ends by a flattened oval plate, the **base**, which forms the footplate of the stirrup and is fixed to the margin of the fenestra vestibuli by a ring of ligamentous fibers. Of the two crura, the anterior is shorter and less curved than the posterior.

**ARTICULATIONS OF THE AUDITORY OSSICLES.** The **incudomalleolar joint** is a saddleshaped diarthrosis; it is surrounded by an articular capsule, and the joint cavity is incompletely divided into two by a wedgeshaped articular disc or meniscus. The **incudostapedial joint** is an enarthrosis surrounded by an articular capsule. Some observers have described an articular disc or meniscus in this joint; others regard the joint as a syndesmosis.

**Fig. 13-54.** A, Left stapes. B, Base of stapes, medial surface.

**LIGAMENTS OF THE OSSICLES.** The ossicles are connected with the walls of the tympanic cavity by ligaments: three for the malleus and one each for the incus and stapes (Fig. 13-55).

The **anterior ligament of the malleus** is attached by one end to the neck of the malleus, just above the anterior process, and by the other end to the anterior wall of the tympanic cavity, close to the petrotympanic fissure. Some of its fibers are prolonged through the fissure to reach the spine of the sphenoid bone.

The **superior ligament of the malleus** is a delicate, round bundle that descends from the roof of the epitympanic recess to the head of the malleus.

The **lateral ligament of the malleus** is a triangular band passing from the posterior part of the notch of Rivinus to the head of the malleus. Helmholtz described the anterior ligament and the posterior part of the lateral ligament as forming together the **axis ligament**, around which the malleus rotates.

The **posterior ligament of the incus** is a short, thick band connecting the end of the short crus of the incus to the fossa incudis.

A **superior ligament of the incus** has been described, but it is little more than a fold of mucous membrane.

The vestibular surface and the circumfer-

**Fig. 13-55.** Chain of ossicles and their ligaments, anterior view of a vertical transverse section of the tympanum. (Testut.)

ence of the base of the stapes are covered with hyaline cartilage. The cartilage that encircles the base is attached to the margin of the fenestra vestibuli by a fibrous ring, the **annular ligament of the base of the stapes**.

### **Muscles of the Tympanic Cavity**

These are the tensor tympani and the stapedius (Figs. 13-45; 13-50).

The **tensor tympani** is contained in the bony canal above the osseous portion of the auditory tube, from which it is separated by the septum canalis musculotubarii. It arises from the cartilaginous portion of the auditory tube and the adjoining part of the great wing of the sphenoid, as well as from the osseous canal in which it is contained. Passing posteriorly through the canal, it ends in a slender tendon that enters the tympanic cavity, makes a sharp bend around the extremity of the septum, the **processus cochleariformis**, and is inserted into the manubrium of the malleus, near its root. It is supplied by a branch of the mandibular nerve that passes through the otic ganglion.

The **stapedius** arises from the wall of the conical cavity inside the pyramid. Its tendon emerges from the orifice at the apex of the eminence, and is inserted into the posterior surface of the neck of the stapes. It is supplied by a branch of the facial nerve.

**ACTIONS.** The tensor tympani draws the tympanic membrane medialward, and thus increases its tension. The stapedius pulls the head of the stapes posteriorly, tilting the base and possibly increasing the tension of the fluid within the internal ear. Both muscles have a snubbing action, reducing the oscillations of the ossicles and thereby protecting the inner ear from injury during a loud noise, such as that of a riveting machine.

### **Mucous Membrane of the Tympanic Cavity**

This membrane is continuous with that of the pharynx through the auditory tube. It invests the auditory ossicles, the muscles, and the nerves contained in the tympanic cavity. It forms the medial layer of the tympanic membrane and the lateral layer of the secondary tympanic membrane, and is reflected into the tympanic antrum and mastoid cells, which it lines throughout. It forms several folds that extend from the walls of the tympanic cavity to the ossicles. Of these,

one descends from the roof of the cavity to the head of the malleus and superior margin of the body of the incus; a second invests the stapedius muscle. Other folds invest the chorda tympani nerve and the tensor tympani muscle. These folds separate pouch-like cavities and give the interior of the tympanum a somewhat honey-combed appearance. One of these pouches, the **pouch of Prussak**<sup>1</sup>, is well marked and lies between the neck of the malleus and the membrana flaccida. Two other recesses may be mentioned: they are formed by the mucous membrane that envelops the chorda tympani nerve and are named the **anterior** and **posterior recesses of Tröltsch**<sup>2</sup>. In the tympanic cavity this membrane is pale, thin, slightly vascular, and covered for the most part with columnar ciliated epithelium, but over the pyramidal eminence, ossicles, and tympanic membrane it possesses a flat, nonciliated epithelium. In the tympanic antrum and mastoid cells, its epithelium is also nonciliated. In the osseous portion of the auditory tube the membrane is thin, but in the cartilaginous portion it is thick, highly vascular, and provided with numerous mucous glands. The epithelium that lines the tube is columnar and ciliated.

**VESSELS AND NERVES.** There are six **arteries**, two of which are larger than the others, viz., the tympanic branch of the maxillary artery, which supplies the tympanic membrane and the stylomastoid branch of the posterior auricular artery, which supplies the back part of the tympanic cavity and mastoid cells. The smaller arteries include the following: the petrosal branch of the middle meningeal artery, which enters through the hiatus of the facial canal; a branch from the ascending pharyngeal artery and another from the artery of the pterygoid canal, which accompany the auditory tube; and the tympanic branch from the internal carotid, which is given off in the carotid canal and perforates the thin anterior wall of the tympanic cavity. The **veins** terminate in the pterygoid plexus and the superior petrosal sinus.

The **nerves** constitute the tympanic plexus, which ramifies upon the surface of the promontory, and the chorda tympani, which merely passes through the cavity. The plexus is formed by (1) the tympanic branch of the glossopharyngeal nerve; (2) the caroticotympanic nerves; (3) the lesser petrosal nerve;

<sup>1</sup>Alexander Prussak (1839-1897): A Russian otologist (St. Petersburg).

<sup>2</sup>Anton Friedrich von Tröltsch (1829-1890): A German otologist (Würzburg).

and (4) a branch that joins the greater petrosal nerve.

The **tympanic branch of the glossopharyngeal** (*Jacobson's nerve*<sup>1</sup>) enters the tympanic cavity by an aperture in its floor close to the labyrinthine wall; it divides into branches that ramify on the promontory and enter into the formation of the tympanic plexus.

The **superior and inferior caroticotympanic nerves** from the carotid plexus of sympathetic fibers pass through the wall of the carotid canal and join the tympanic plexus. The branch to the greater petrosal passes through an opening on the labyrinthine wall, anterior to the fenestra vestibuli.

The **lesser petrosal nerve** is a continuation of the tympanic branch of the glossopharyngeal nerve beyond the tympanic plexus. It penetrates the bone near the geniculate ganglion of the facial nerve, with which it communicates by a filament. It continues through the bone and enters the middle cranial fossa through a small aperture situated lateral to the hiatus of the facial canal on the anterior surface of the petrous portion of the temporal bone. It leaves the middle fossa through a fissure or foramen of its own or through the foramen ovale, and ends in the otic ganglion, constituting its root and supplying it with preganglionic parasympathetic fibers.

The **branches of distribution** of the tympanic plexus supply the mucous membrane of the tympanic cavity, the fenestra vestibuli, the fenestra cochleae, and the auditory tube. The lesser petrosal may be looked upon as the continuation of the tympanic branch of the glossopharyngeal nerve through the plexus to the otic ganglion.

In addition to the tympanic plexus, there are nerves that supply the muscles. The tensor tympani is supplied by a branch from the mandibular nerve that passes through the otic ganglion, and the stapedius is supplied by a branch from the facial nerve.

The **chorda tympani nerve** crosses the tympanic cavity (Fig. 13-47). It leaves the facial canal about 6 mm before the facial nerve emerges from the stylomastoid foramen. It runs back upward in a canal of its own, almost parallel with the facial canal, and enters the tympanic cavity through the iter chordae posterior, where it becomes invested with mucous membrane. It traverses the tympanic cavity across the medial surface of the tympanic membrane and over the upper part of the manubrium of the malleus to the carotid wall, where it makes exit through the iter chordae anterior (*canal of Huguier*).

## INTERNAL EAR OR LABYRINTH

The **internal ear** is the essential part of the organ of hearing, the ultimate distribution of the vestibulocochlear nerve. It is called the

**labyrinth**, from the complexity of its shape, and consists of two parts: the **osseous labyrinth**, a series of cavities within the petrous part of the temporal bone, and the **membranous labyrinth**, a series of communicating membranous sacs and ducts contained within the bony cavities.

### Osseous Labyrinth

The **osseous labyrinth** (Figs. 13-56; 13-57) consists of three parts: **vestibule**, **semicircular canals**, and **cochlea**. These are cavities hollowed out of the substance of the bone and lined by periosteum; they contain a clear fluid, the **perilymph**, in which the membranous labyrinth is suspended.

**VESTIBULE.** The vestibule is the central part of the osseous labyrinth. It is situated medial to the tympanic cavity, posterior to the cochlea, and anterior to the semicircular canals. It is somewhat ovoid but flat transversely; it measures about 5 mm sagittally and vertically, and about 3 mm across. In its *lateral* or *tympanic wall* is the **fenestra vestibuli**, which in the intact body is closed by the base of the stapes and annular ligament. On its *medial wall* is a small circular depression, the **recessus sphericus**, which is perforated at its anterior and inferior part by several minute holes (**macula cribrosa media**) for the passage of filaments of the vestibulocochlear nerve to the saccule. Posterior to this depression is an oblique ridge, the **crista vestibuli**, the anterior end of which is named the **pyramid of the vestibule**. This ridge bifurcates to enclose a small depression, the

**FIG. 13-56.** Right osseous labyrinth with spongy bone removed. Lateral view.

<sup>1</sup>Ludwig Levin Jacobson (1783-1843): A Danish anatomist and physician (Copenhagen).

**fossa cochlearis**, which is perforated by a number of holes for the passage of filaments of the vestibulocochlear nerve that supply the vestibular end of the ductus cochlearis. At the posterior part of the medial wall is the orifice of the **aquaeductus vestibuli**, which extends to the posterior surface of the petrous portion of the temporal bone. It transmits a small vein and contains a tubular prolongation of the membranous labyrinth, the **ductus endolymphaticus**, which ends in a cul-de-sac between the layers of the dura mater within the cranial cavity.

On the superior wall or roof is a transversely oval depression, the **recessus ellipticus**, which is separated from the recessus sphericus by the crista vestibuli already mentioned. The pyramid and adjoining part of the recessus ellipticus are perforated by a number of holes (**macula cribrosa superior**). The apertures in the pyramid transmit the nerves to the utricle; those in the recessus ellipticus transmit the nerves to the ampullae of the anterior and lateral semicircular

ducts. Posteriorly are the five orifices of the semicircular canals. Anteriorly is an elliptical opening that communicates with the scala vestibuli of the cochlea.

**BONY SEMICIRCULAR CANALS.** There are three bony semicircular canals: **anterior**, **posterior**, and **lateral**; these are situated superior and posterior to the vestibule. They are unequal in length and compressed from side to side; each describes the greater part of a circle. Each measures about 0.8 mm in diameter, and presents a dilatation at one end, called the **ampulla**, which measures more than twice the diameter of the tube. They open into the vestibule by five orifices, with one of the apertures being common to two of the canals.

The **anterior semicircular canal** (superior semicircular canal); 15 to 20 mm long, is vertical in direction and is placed transversely to the long axis of the petrous portion of the temporal bone (Fig. 13-58), on the anterior surface of which its arch forms a round projection. It describes about two-thirds of a

**FIG. 13-57.** The right bony labyrinth with the semicircular canals and the cochlea opened. (Redrawn after Sobotta.)

Fig. 13-58. Interior of right osseous labyrinth.

circle. Its lateral extremity is ampullated and opens into the superior part of the vestibule; the opposite end joins with the superior part of the posterior canal to form the **crus commune**, which opens into the superior and medial part of the vestibule.

The **posterior semicircular canal**, also vertical, is directed posteriorly, nearly parallel to the posterior surface of the petrous bone. It is the longest of the three canals, measuring from 18 to 22 mm. Its inferior or ampullated end opens into the inferior and posterior part of the vestibule; its superior end opens into the crus commune already mentioned.

The **lateral or horizontal canal** (external semicircular canal) is the shortest of the three canals. It measures 12 to 15 mm, and its arch is directed horizontally lateralward; thus, each semicircular canal stands at right angles to the other two. Its ampullated end corresponds to the superior and lateral angle of the vestibule, just above the fenestra vestibuli, where it opens close to the ampullated end of the superior canal. Its opposite end opens at the superior and posterior part of the vestibule. The lateral canal of one ear is very nearly in the same plane as that of the other, while the anterior canal of one ear is nearly parallel to the posterior canal of the other.

**COCHLEA** (Figs. 13-56; 13-57). The cochlea bears some resemblance to a common snail shell. It forms the anterior part of the labyrinth, is conical, and is placed almost hori-

zontally in front of the vestibule. Its **apex** (cupula) is directed anteriorly and laterally, with a slight inclination inferiorly, toward the labyrinthine wall of the tympanic cavity. Its base corresponds with the bottom of the internal acoustic meatus and is perforated by numerous apertures for the passage of the cochlear division of the vestibulocochlear nerve.

The cochlea measures about 5 mm from base to apex, and its breadth across the base is about 9 mm. It consists of: (1) a conical-shaped central axis, the **modiolus**; (2) a canal, the inner wall of which is formed by the central axis, wound spirally around it for two and three-quarter turns, from the base to the apex; and (3) a delicate lamina, the **osseous spiral lamina**, which projects from the modiolus, and, following the windings of the canal, partially subdivides it into two. In the intact body, the **basilar membrane** stretches from the free border of this lamina to the outer wall of the bony cochlea and completely separates the canal into two passages, which, however, communicate with each other at the apex of the modiolus by a small opening, named the **helicotrema** (Fig. 13-59).

The **modiolus** is the conical central axis or pillar of the cochlea. Its base is broad and appears at the bottom of the internal acoustic meatus, where it corresponds with the area cochleae; it is perforated by numerous orifices that transmit filaments of the cochlear division of the vestibulocochlear nerve.

The nerves for the first turn and a half pass through the foramina of the tractus spiralis foraminosus; those for the apical turn pass through the foramen centrale. The canals of the tractus spiralis foraminosus pass through the modiolus and successively bend outward to reach the attached margin of the lamina spiralis ossea. Here they become enlarged and by their apposition form the **spiral canal of the modiolus**, which follows the course of the attached margin of the osseous spiral lamina and lodges the **spiral ganglion** (ganglion of Corti<sup>1</sup>). The foramen centrale is continued into a canal that runs through the middle of the modiolus to its apex. The modiolus diminishes rapidly in size in the second and succeeding coil.

The bony canal of the cochlea takes two and three-quarter turns around the modiolus. It is about 30 mm long and diminishes gradually in diameter from the base to the summit, where it terminates in the **cupula**, which forms the apex of the cochlea (Fig. 13-59). The beginning of this canal is about 3 mm in diameter; it diverges from the modiolus toward the tympanic cavity and vestibule and presents three openings. One open-

ing, the **fenestra cochleae**, communicates with the tympanic cavity; in the intact body this aperture is closed by the **secondary tympanic membrane**. Another opening has an elliptical form and opens into the vestibule. The third opening is the aperture of the aquaeductus cochleae, which leads to a minute, funnel-shaped canal that opens on the inferior surface of the petrous part of the temporal bone. It transmits a small vein, and also forms a communication between the subarachnoid cavity and the scala tympani.

The **osseous spiral lamina** is a bony shelf or ledge that projects from the modiolus into the interior of the canal, and like the canal, takes two and three-quarter turns around the modiolus. It reaches about half way toward the outer wall of the tube and partially divides its cavity into two passages or *scalae*, of which the superior is named the **scala vestibuli**, while the inferior is termed the **scala tympani** (Fig. 13-59). Near the summit of the cochlea, the lamina ends in a hook-shaped process, the **hamulus laminae spiralis**; this assists in forming the boundary of a small opening, the **helicotrema**, through which the two *scalae* communicate with each other. From the spiral canal of the modiolus numerous canals pass outward through the osseous spiral lamina as far as

<sup>1</sup>Alfonso Corti (1822-1888): An Italian anatomist (Sardinia).

**Fig. 13-59.** The cochlea and vestibule, viewed from above. All the hard parts that form the roof of the internal ear have been removed with a saw.

its free edge. In the inferior part of the first turn a second bony lamina, the **secondary spiral lamina**, projects inward from the outer wall of the bony tube; it does not, however, reach the primary osseous spiral lamina, so that if viewed from the vestibule a narrow fissure, the **vestibule fissure**, is seen between them.

The osseous labyrinth is lined by an exceedingly thin fibrous membrane. The attached surface is rough, fibrous, and closely adherent to the bone; its free surface is smooth, pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the **perilymph**. A delicate tubular process of this membrane is prolonged along the aqueduct of the cochlea to the inner surface of the dura mater.

### Membranous Labyrinth

The **membranous labyrinth** (Figs. 13-60; 13-61; 13-62) is lodged within the bony cavities just described, and has the same general form as these; it is, however, considerably smaller, and is partly separated from the bony walls by a fluid, the **perilymph**. In certain places it is fixed to the walls of the cavity. The membranous labyrinth also contains fluid, the **endolymph**, and the ramifications of the vestibulocochlear nerve are distributed on its walls.

Within the osseous vestibule the membranous labyrinth does not quite preserve the form of the bony cavity, but consists of two membranous sacs, the **utricle** and the **saccul**.

**UTRICLE.** The utricle, the larger of the two sacs, is oblong, compressed transversely, and occupies the superior and posterior part of the vestibule, lying in contact with the recessus ellipticus and the part inferior to it. That portion which is lodged in the recess forms a sort of pouch or cul-de-sac, the floor and anterior wall of which are thick and form the **macula of the utricle**, which receives the utricular filaments of the vestibulocochlear nerve. The cavity of the utricle communicates behind with the semicircular ducts by five orifices. From its anterior wall is given off the **ductus utriculosaccularis**, which opens into the ductus endolymphaticus.

**SACCLE.** The saccul is the smaller of the two vestibular sacs; it has a globular shape and lies in the recessus sphericus near the opening of the scala vestibuli of the cochlea. Its anterior part exhibits an oval thickening, the **macula of the saccul**, to which are distributed the saccular filaments of the vestibulocochlear nerve. Its cavity does not directly communicate with that of the utricle. From the posterior wall a canal, the **ductus endolymphaticus**, is given off; this duct is joined by the ductus utriculosaccularis, and then passes along the aqueduct vestibuli and ends in a blind pouch (**sacculus endolymphaticus**) on the posterior surface of the petrous portion of the temporal bone, where it is in contact with the dura mater. From the inferior part of the saccul a short tube, the **ductus reuniens** (*canalis reuniens* of Hensen<sup>1</sup>) passes inferiorly and opens into the ductus cochlearis near its vestibular extremity (Fig. 13-60).

**SEMICIRCULAR DUCTS.** The semicircular ducts (membranous semicircular canals) (Figs. 13-61; 13-62) are about one-fourth of the diameter of the osseous canals, but in number, shape, and general form they are precisely similar, and each has an ampulla at one end. They open by five orifices into the utricle, one opening being common to the medial end of the anterior duct and the superior end of the posterior duct. In each ampulla, the wall is thickened and projects into the cavity as a fiddle-shaped, transversely placed elevation, the **ampullary crest**, in which the nerves end.

The utricle, saccul, and semicircular ducts are held in position by numerous fi-

brous bands that stretch across the space between them and the bony walls.

**STRUCTURE OF THE UTRICLE, SACCULE, AND SEMICIRCULAR DUCTS** (Fig. 13-63). The walls of the utricle, saccule, and semicircular ducts consist of three layers. The outer layer is a loose and flocculent structure, apparently composed of ordinary fibrous tissue containing blood vessels and some pigment cells. The middle layer, thicker and more transparent than the outer, forms a homogeneous *membrana propria* and has numerous papilliform projections on its internal surface, especially in the semicircular ducts, which exhibit an appearance of longitudinal fibrillation on the addition of acetic acid. The inner layer is formed of polygonal nucleated epithelial cells. In the maculae of the utricle and saccule and in the ampullary crests of the semicircular ducts, the middle coat is thick and the epithelium is columnar and consists of **supporting cells** and **hair cells**. The supporting cells are fusiform; their deep ends are attached to the *membrana propria* while their free extremities are united to form a thin cuticle. The **neuroepithelium** or hair cells are flask-shaped, and their deep, rounded ends do not reach the *membrana propria*, but lie between the supporting cells. The deep part of each contains

a large nucleus, while its more superficial part is granular and pigmented. The free end is surmounted by a long, tapering, hair-like filament that projects into the cavity. The filaments of the vestibulocochlear nerve enter these parts, and having pierced the outer and middle layers, they lose their myelin sheaths and their axons ramify between the hair cells.

Numerous small round bodies termed **otoconia** (*statoconia*), each consisting of a mass of minute crystalline grains of carbonate of lime held together in a mesh of gelatinous tissue, are suspended in the endolymph in contact with the free ends of the hairs projecting from the maculae.

**COCHLEAR DUCT.** The cochlear duct (*ductus cochlearis*; *membranous cochlea*; *scala media*) consists of a spirally arranged tube enclosed in the bony canal of the cochlea and lying along its outer wall.

As already stated, the osseous spiral lamina extends only part of the distance between the modiolus and the outer wall of the cochlea, while the **basilar membrane** (*membrana spiralis*) stretches from its free edge to the outer wall of the cochlea and completes the roof of the *scala tympani*. A second and more delicate membrane, the **vestibular membrane** (Reissner's mem-

**FIG. 13-63.** Transverse section of a human semicircular canal and duct. (After Rüdinger.)

brane<sup>1</sup>), extends from the thickened periosteum covering the osseous spiral lamina to the outer wall of the cochlea, where it is attached at some little distance above the outer edge of the basilar membrane. A canal is thus shut off between the scala tympani and the scala vestibuli; this is the **cochlear duct** or **scala media** (Figs. 13-64; 13-65). It is triangular on transverse section, its roof being formed by the vestibular membrane, its outer wall of the periosteum lining the bony canal, and its floor by the membrana spiralis and the outer part of the osseous spiral lamina. Its extremities are closed, the upper is termed the **lagena** and is attached to the cupula at the upper part of the helico-

trema; the inferior is lodged in the recessus cochlearis of the vestibule. Near the inferior end, the ductus cochlearis becomes continuous with the sacculus by means of a narrow, short canal, the **ductus reuniens** (Fig. 13-60).

The **spiral organ of Corti** rests upon the basilar membrane. The vestibular membrane is thin, homogeneous, and covered on its superior and inferior surfaces by a layer of epithelium. The periosteum, forming the outer wall of the cochlear duct, is greatly thickened and altered in character, and is called the **spiral ligament**. It projects inward below as a triangular prominence, the **basilar crest**, which gives attachment to the outer edge of the basilar membrane; immediately above the crest is a concavity, the **sulcus spiralis externus**. The upper portion of the spiral ligament contains numerous

<sup>1</sup>Ernst Reissner (1824-1878): A German anatomist (Dorpat, then Breslau).

**FIG. 13-64.** A section through the left temporal bone. (Drawn from a section prepared at the Fehrens Institute, kindly lent by Prof. J. Kirk.)

capillary loops and small blood vessels, and it is termed the **stria vascularis**.

The osseous spiral lamina consists of two plates of bone, and between these are the canals for the transmission of the filaments of the vestibulocochlear nerve. On the upper plate of that part of the lamina which is outside the vestibular membrane, the perosteum is thickened to form the **limbus laminae spiralis**. This ends externally in a concavity. The **sulcus spiralis internus** (Fig. 13-65) represents, in section, the form of the letter C; the upper part, formed by the overhanging extremity of the limbus, is named the **vestibular lip**; the lower part, prolonged and tapering, is called the **tympanic lip**, and is perforated by numerous foramina for the passage of the cochlear nerve fibers. The upper surface of the vestibular lip is intersected at right angles by a number of furrows, between which are numerous eleva-

tions; these present the appearance of teeth along the free surface and margin of the lip, and they have been named **dentes acoustici**. The limbus is covered by a layer of what appears to be squamous epithelium, but the deeper parts of the cells with their contained nuclei occupy the intervals between the elevations and between the auditory teeth. This layer of epithelium is continuous on the one hand with that lining the sulcus spiralis internus, and on the other with that covering the undersurface of the vestibular membrane.

**BASILAR MEMBRANE.** The basilar membrane stretches from the tympanic lip of the osseous spiral lamina to the basilar crest and consists of two parts, an inner and an outer. The inner part is thin and is named the **zona arcuata**; it supports the spiral organ of Corti. The outer is thicker and striated and is termed the **zona pectinata**. The undersurface

FIG. 13-65. A section through the second turn of the cochlea indicated in the previous figure. (Mallory's stain.)

of the membrane is covered by a layer of vascular connective tissue; one of the vessels in this tissue is somewhat larger than the rest, and is named the **vas spirale**.

**STRUCTURE OF THE ORGAN OF CORTI.** The **spiral organ** or **organ of Corti** (Fig. 13-66) is composed of a series of epithelial structures placed upon the inner part of the basilar membrane. The average length is 31.5 mm. The more central of these structures are two rows of rod-like bodies, the **inner and outer rods** or **pillars of Corti**. The bases of the rods are supported on the basilar membrane, those of the inner row at some distance from those of the outer row. The two rows incline toward each other, and coming into contact superiorly, enclose between them and the basilar membrane a triangular tunnel, the **tunnel of Corti**. On the inner side of the inner rods is a single row of hair cells, and on the outer side of the outer rods are three or four rows of similar cells, together with certain supporting cells termed the cells of Deiters and Hensen. The free ends of the outer hair cells occupy a series of apertures in a net-like membrane, the **reticular membrane**, and the entire organ is covered by the **tectorial membrane**.

**Rods of Corti.** Each consists of a base or foot-plate and elongated part or body, and an upper end or head. The body of each rod is finely striated, but in the head there is an oval, nonstriated portion that stains deeply with carmine. Occupying the angles between the rods and the basilar membrane are nucleated cells that partly envelop the

rods and extend onto the floor of Corti's tunnel; these may be looked upon as the undifferentiated parts of the cells from which the rods have been formed.

The **inner rods** number nearly 6000, and their bases rest on the basilar membrane close to the tympanic lip of the sulcus spiralis internus. The shaft or body of each is sinuously curved and forms an angle of about  $60^\circ$  with the basilar membrane. The head resembles the proximal end of the ulna and presents a deep concavity that accommodates a convexity on the head of the outer rod. The headplate, or portion overhanging the concavity, overlaps the headplate of the outer rod.

The **outer rods**, numbering nearly 4000, are longer and more obliquely set than the inner rods, forming with the basilar membrane an angle of about  $40^\circ$ . Their heads are convex internally; they fit into the concavities on the heads of the inner rods and are continued outward as thin flattened plates, termed **phalangeal processes**, which unite with the phalangeal processes of Deiters' cells to form the reticular membrane.

**Hair Cells.** The hair cells are short columnar cells; their free ends are on a level with the heads of Corti's rods, and each is surmounted by about 20 hair-like processes arranged in the form of a crescent with its concavity directed inward. The deep ends of the cells reach about half way along Corti's rods, and each contains a large nucleus; in contact with the deep ends of the hair cells are the terminal filaments of the cochlear division

FIG. 13-66. Section through the spiral organ of Corti. Magnified. (G. Retzius.)

of the vestibulocochlear nerve. The inner hair cells, about 3500 in number, are arranged in a single row on the medial side of the inner rods. Because their diameters are greater than those of the rods, each hair cell is supported by more than one rod. The free ends of the inner hair cells are encircled by a cuticular membrane that is fixed to the heads of the inner rods. Adjoining the inner hair cells are one or two rows of columnar supporting cells, which, in turn, are continuous with the cubical cells lining the sulcus spiralis internus. The outer hair cells number about 12,000 and are nearly twice as long as the inner. In the basal coil of the cochlea they are arranged in three regular rows; in the apical coil, in four somewhat irregular rows. The receptors for high tones are located in the basal turn of the cochlea.

**Supporting Cells.** Between the rows of the outer hair cells are rows of supporting cells, called the **cells of Deiters**<sup>1</sup>; their expanded bases are planted on the basilar membrane, while the opposite end of each presents a clubbed extremity or **phalangeal process**. Immediately to the outer side of Deiters' cells are five or six rows of columnar cells, the **supporting cells of Hensen**. Their bases are narrow, while their upper parts are expanded and form a rounded elevation on the floor of the ductus cochlearis. The columnar cells lying outside Hensen's cells are termed the **cells of Claudius**.<sup>2</sup> A space exists between the outer rods of Corti and the adjacent hair cells; this is called the **space of Nuel**.<sup>3</sup>

**Reticular Lamina.** The **reticular lamina** is a delicate framework perforated by rounded holes which are occupied by the free ends of the outer hair cells. It extends from the heads of the outer rods of Corti to the external row of the outer hair cells, and is formed by several rows of minute fiddle-shaped cuticular structures, called **phalanges**, between which are circular apertures containing the free ends of the hair cells. The innermost row of phalanges consists of the phalangeal processes of the outer rods of Corti; the outer rows are formed by the modified free ends of Deiters' cells.

<sup>2</sup>Friedrich Matthias Claudius (1822-1869): An Austrian anatomist.

<sup>3</sup>Jean Pierre Nuel (1847-1920): A Belgian physiologist and otologist (Ghent and Liège).

**Tectorial Membrane.** Covering the sulcus spiralis internus and the spiral organ of Corti is the **tectorial membrane**, which is attached to the limbus laminae spiralis close to the inner edge of the vestibular membrane. Its inner part is thin and overlies the auditory teeth of Huschke;<sup>4</sup> its outer part is thick, and along its lower surface, opposite the inner hair cells, is a clear band, named **Hensen's stripe** owing to the intercrossing of its fibers. The lateral margin of the membrane is much thinner. It consists of fine, colorless fibers embedded in a transparent matrix of a soft collagenous, semisolid character with marked adhesiveness; the matrix may be a variety of soft keratin. The general transverse direction of the fibers inclines from the radius of the cochlea toward the apex.

**Nerves.** The **vestibulocochlear nerve** (*acoustic nerve; n. statoacusticus; nerve of hearing*) divides near the bottom of the internal acoustic meatus into an anterior or cochlear branch and a posterior or vestibular branch.

The **vestibular nerve** supplies the utricle, the saccule, and the ampullae of the semicircular ducts. On the trunk of the nerve, within the internal acoustic meatus, is the **vestibular ganglion** (*ganglion of Scarpa*<sup>5</sup>); the fibers of the nerve arise from the cells of this ganglion. On the distal side of the ganglion the nerve splits into a superior, an inferior, and a posterior branch. The filaments of the *superior branch* are transmitted through the foramina in the area vestibularis superior, and end in the macula of the utricle and in the ampullae of the anterior and lateral semicircular ducts. Those of the *inferior branch* traverse the foramina in the area vestibularis inferior and end in the macula of the saccule. The *posterior branch* runs through the foramen singulare at the posteroinferior part of the bottom of the meatus and divides into filaments to supply the ampulla of the posterior semicircular duct.

The **cochlear nerve** divides into numerous filaments at the base of the modiolus. Those for the basal and middle coils pass through the foramina in the tractus spiralis foraminosus and those for the apical coil pass through the canalis centralis; the nerves bend outward to pass between the lamellae of the osseous spiral lamina. Occupying the spiral canal of the modiolus is the **spiral ganglion of the cochlea** (*ganglion of Corti*) (Fig. 13-65), which consists of bipolar nerve cells that constitute the cells of origin of this nerve. Reaching the outer edge of the osseous spiral lamina, the fibers of the nerve pass through the foramina in the tympanic lip. Some end

<sup>4</sup>Emil Huschke (1797-1858): A German anatomist (Jena).

<sup>5</sup>Anthony Scarpa (1747-1832): Italian anatomist and surgeon (Pavia).

by arborizing around the bases of the inner hair cells, while others pass between Corti's rods and across the tunnel to end in a similar manner in relation to the outer hair cells. The cochlear nerve gives off a vestibular branch to supply the vestibular end of the ductus cochlearis; the filaments of this branch pass through the foramina in the fossa cochlearis.

**Vessels.** The arteries of the labyrinth are the internal auditory artery, which comes from the basilar artery, and the stylomastoid artery, which comes from the posterior auricular artery. The internal auditory artery divides at the bottom of the internal

acoustic meatus into two branches: cochlear and vestibular. The cochlear branch subdivides into 12 or 14 twigs that traverse the canals in the modiolus and are distributed, in the form of a capillary network, in the lamina spiralis and basilar membrane. The vestibular branches are distributed to the utricle, saccule, and semicircular ducts.

The veins of the vestibule and semicircular canals accompany the arteries, and, receiving those of the cochlea at the base of the modiolus, unite to form the internal auditory veins, which end in the posterior part of the superior petrosal sinus or in the transverse sinus.

## The Integument

Covering the surface of the body and sheltering it from injurious influences in the environment is the **skin** or **integument**. It protects the deeper tissues from injury, from drying, and from invasion by foreign organisms; it contains the peripheral endings of many of the sensory nerves. It plays an important part in the regulation of the body temperature and also has limited excretory and absorbing powers. It consists principally of a layer of dense connective tissue, named the **dermis** (*corium*, *cutis vera*), and an external covering of epithelium, termed the **epidermis** or **cuticle**. On the surface of the former layer are **sensitive** and **vascular papillae**; within or beneath it are certain organs with special functions, namely, the **sudoriferous** and **sebaceous glands** and the **hair follicles**.

### Development

The epidermis and its appendages (hairs, nails, sebaceous and sweat glands) are developed from the ectoderm; the corium or true skin is of mesodermal origin. About the fifth week of fetal development, the epidermis consists of two layers of cells, the deeper one corresponding to the rete mucosum. The

subcutaneous fat appears about the fourth month, and the papillae of the true skin, about the sixth month. A considerable desquamation of epidermis takes place during fetal life, and this desquamated epidermis, mixed with sebaceous secretion, constitutes the **vernix caseosa**, with which the skin is smeared during the last three months of fetal life. The nails are formed at the third month and begin to project from the epidermis about the sixth month. The hairs appear between the third and fourth months in the form of solid downgrowths of the deeper layer of the epidermis, the growing extremities of which become inverted by papillary projections from the corium. The central cells of the solid downgrowths undergo alteration to form the hair, while the peripheral cells are retained to form the lining cells of the hair follicle. About the fifth month the fetal hairs (**lanugo**) appear first on the head and then on the other parts; they drop after birth and give place to the permanent hairs. The cellular structures of the sudoriferous and sebaceous glands are formed from the ectoderm, whereas the connective tissue and blood vessels are derived from the mesoderm. All the sweat glands are fully formed at birth; they begin to develop as early as the fourth month.

### Structure

**EPIDERMIS.** The **epidermis**, **cuticle**, or **scarf skin** is nonvascular, consists of stratified epithelium, and is accurately molded over the papillary layer of the dermis. It varies in thickness in different parts of the body. In some situations, as in the palms of the hands and soles of the feet, it is thick, hard, and horny in texture. The more superficial layers of cells, called the **horny layer** (*stratum corneum*), may be separated by maceration from a deeper stratum, which is called the **stratum mucosum** and which consists of several layers of differently shaped cells. The free surface of the epidermis is marked by a network of linear furrows of variable size, dividing the surface into polygonal or lozenge-shaped areas. Some of these furrows are large, such as those opposite the flexures of the joints, and they correspond to folds in the dermis. In other situations, as upon the back of the hand, they are exceedingly fine and intersect one another at various angles.

Upon the palmar surfaces of the hands and fingers and upon the soles of the feet, the epidermal ridges are distinct and disposed in curves; they depend upon the large size and peculiar arrangements of the papillae upon which the epidermis is placed. These ridges increase friction between contact surfaces to prevent slipping in walking or prehension. The direction of the ridges is at right angles to the force that tends to produce slipping or to the resultant of such forces when these forces vary in direction. In each individual the lines of the tips of the fingers and thumbs form distinct patterns unlike those of any other person. A method of determining the identity of a person is based on this fact by making impressions or **fingerprints** of these lines. The deep surface of the epidermis is accurately molded upon the papillary layer of the dermis, the papillae being covered by a basement membrane. When the epidermis is lifted off by maceration and inverted, it presents on its undersurface pits or depressions that correspond to the papillae, and ridges corresponding to the intervals between them. Fine tubular prolongations are continued from this layer into the ducts of the sudoriferous and sebaceous glands.

The **stratified squamous epithelium** of the epidermis is composed of several layers named according to various properties such as shape of cells, texture, composition and

position. Beginning with the deepest, they are: (a) stratum basale, (b) stratum spinosum, (c) stratum granulosum, (d) stratum lucidum, and (e) stratum corneum.

The **stratum basale**, the deepest layer, is composed of columnar or cylindrical cells, giving it an alternate name **stratum cylindricum**. The ends of the cells in contact with the basement membrane have toothlike protoplasmic projections that fit into sockets in the membrane and appear to anchor the cells to the underlying dermis. The cells of this layer undergo division by mitosis, supplying new cells to make up for the continual loss of surface layers from abrasion. This layer has been appropriately named the **stratum germinativum** (Fig. 14-1).

The **stratum spinosum** is composed of several layers of polygonal cells, the number depending upon the area of the body from which the skin is taken. As a result of the slight shrinkage caused by technical procedures, these cells in ordinary histologic preparations appear to have cytoplasmic bridges connecting them with their neighbors. When they are pulled apart, they appear to have minute spines on their surface, giving them the name **prickle cells**. Electron microscopic studies have shown that each cell adheres to its neighbors at particular points called **desmosomes**, and that these points are drawn out into the spines by

**Fig. 14-1.** Section through scalp of adult cadaver. 5 ×.

shrinkage. Ultrastructural studies have also shown that the cytoplasm of these cells contains minute fibrils, some of which are oriented toward the desmosomes. In light microscopic preparations these fibrils may be visible, and since they are associated with the desmosomes, they give the impression of running between cells and are called **tonofibrils**.

The **stratum granulosum** is composed of two or three rows of flat cells that lie parallel with the surface. They contain numerous large granules that stain deeply with hematoxylin. They are composed of **keratohyalin**, a substance that apparently is transformed into keratin in more superficial layers.

The **stratum lucidum** appears to be a homogenous translucent band, much thinner than the strata on either side of it. The cells contain droplets of **eleidin** and their nuclei and cell boundaries are not visible.

The **stratum corneum** is composed of squamous plates of scales fused together to make the outer horny layer. These plates are the remains of the cells and contain a fibrous protein, **keratin**. The most superficial layer sloughs off or desquamates. The thickness of this layer is correlated with the trauma to which an area is subjected, being very thick on the palms and soles but thin over protected areas.

**PIGMENTATION.** The black color of the skin in the Negro and the tawny color among some of the white races are due to the presence of pigment in the cells of the epidermis. This pigment is especially distinct in the cells of the stratum basale and is similar to that found in the cells of the pigmented layer of the retina. As the cells approach the surface and desiccate, the color becomes partially lost; the disappearance of the pigment from the superficial layers of the epidermis, however, is difficult to explain.

The pigment (**melanin**) consists of small dark brown or black granules, closely packed together within the cells, but not involving the nucleus.

The main purpose of the epidermis is protection. As the surface is worn away, new cells are supplied, and thus the true skin, the vessels, and the nerves that it contains are defended against damage.

**DERMIS.** The **dermis**, **corium**, **cutis vera** or **true skin** is tough, flexible, and elastic. Its thickness varies in different parts of the body. Thus it is very thick in the palms of

the hands and soles of the feet. It is thicker on the dorsal aspect of the body than on the ventral aspects, and on the lateral sides of the limbs than on the medial sides. In the eyelids, scrotum, and penis, it is exceedingly thin and delicate.

The dermis consists of felted connective tissue, with a varying amount of elastic fibers and numerous blood vessels, lymphatics, and nerves. The connective tissue is arranged in two layers: a **deeper** or **reticular layer**, and a **superficial** or **papillary layer** (Fig. 14-2).

Smooth muscle cells are found in the dermis and the subcutaneous layers of the scrotum, penis, labia majora, and nipples. In the mammary papilla, the smooth muscle cells are disposed in circular bands and radiating bundles arranged in superimposed laminae. Where there are hairs, discrete bundles of smooth muscle called the **arrectores pilorum** are attached in the superficial layers of the corium and near the base of each hair follicle.

The **papillary layer** (*stratum papillare*; *superficial layer*; *corpus papillare of the corium*) consists of numerous small, highly sensitive, and vascular eminences, the **papillae**, which rise perpendicularly from its surface. The papillae are minute conical eminences with rounded or blunted extremities; occasionally they are divided into two or more parts and are received into corresponding pits on the undersurface of the cuticle. On the general surface of the body, especially in parts endowed with slight sensibility, they are few in number and exceedingly minute, but in some situations, as upon the palmar surfaces of the hands and fingers and the plantar surfaces of the feet and toes, the papillae are long, large, closely aggregated, and arranged in parallel curved lines, forming the elevated ridges seen on the free surface of the epidermis. Each ridge contains two rows of papillae, between which the ducts of the sudoriferous glands pass outward to open on the summit of the ridge. Each papilla consists of small and closely interlacing bundles of finely fibrillated tissue with a few elastic fibers; within this tissue is a capillary loop, and in some papillae, especially in the palms of the hand and the fingers, there are tactile corpuscles (Fig. 14-3).

The **reticular layer** (*stratum reticulare*; *deep layer*) consists of fibroelastic connec-

**Fig. 14-2.** Section through the skin of the human foot, cut perpendicularly to the surface. (From Rauber-Kopsch, *Lehrbuch u. Atlas d. Anatomie d. Menschen*, 19th ed., Vol. II, Georg Thieme Verlag, Stuttgart, 1955.)

**Fig. 14-3.** Vascular and sensory papillae in the skin of the human foot. (From Rauber-Kopsch, *Lehrbuch u. Atlas d. Anatomie d. Menschen*, 19th ed., Vol. II, Georg Thieme Verlag, Stuttgart, 1955.)

tive tissue, which is composed chiefly of collagenous bundles but contains yellow elastic fibers in varying number in different parts of the body. The cells are principally fibroblasts and histiocytes, but other types may be found. Near the papillary layer the collagenous bundles are small and compactly arranged; in the deeper layers they are larger and coarser, and between their meshes are sweat glands, sebaceous glands, hair shafts or follicles, and small collections of fat cells. The deep surface of the reticular layer merges with the adipose tissue of the subcutaneous fascia.

**CLEAVAGE LINES OF THE SKIN** (Langer's lines<sup>1</sup>). When a sharp conical instrument is used to make a penetrating wound, it does not leave a round hole in the skin, as might be expected, but a slit such as would be expected from a flat blade. Maps of the directions of these slits from puncture wounds over all parts of the body have been made from dissecting room material (Figs. 14-4;

<sup>1</sup>Carl Ritter von Eldenberg von Langer (1819-1887): Austrian anatomist (Vienna).

**FIG. 14-4.** Cleavage lines (Langer's lines) of the skin. Trunk and extremities. (Eller.)

14-5). These maps indicate that there are definite lines of **tension** or **cleavage lines** within the skin that are characteristic for each part of the body. In microscopic sections cut parallel with these lines, most of the collagenous bundles of the reticular layer are cut longitudinally, while in sections cut across the lines, the bundles are in cross section. The cleavage lines correspond closely with the crease lines on the surface of the skin in most parts of the body. The pattern of the cleavage lines, according to Cox (1941), varies with body configuration, but is constant for individuals of similar build regardless of age. There are limited areas of the body in which the orientation of the bundles is irregular and confused. The cleavage lines are of particular interest to the surgeon because an incision made parallel to the lines heals with a fine linear scar, while an incision across the lines may set up irregular tensions that result in an unsightly scar.

**FIG. 14-5.** Cleavage lines (Langer's lines) of the skin. Head and neck. (Eller.)

**VESSELS AND NERVES.** The arteries supplying the skin form a network in the subcutaneous tissue, branches of which supply the sudoriferous glands, the hair follicles, and the fat. Other branches unite in a plexus immediately beneath the dermis; from this plexus, fine capillary vessels pass into the papillae, forming, in the smaller ones, a single capillary loop, but in the larger, a more or less convoluted vessel. The lymphatic vessels of the skin form two networks, superficial and deep, which communicate with each other and with those of the subcutaneous tissue by oblique branches.

The nerves of the skin terminate partly in the epidermis and partly in the corium; at their terminals are found various types of nerve endings.

## Appendages of the Skin

The appendages of the skin are the **nails**, the **hairs**, and the **sudoriferous** and **sebaceous glands** with their ducts.

**NAILS.** The nails (ungues) (Fig. 14-6) are flattened, elastic structures of a horny texture placed upon the dorsal surfaces of the

terminal phalanges of the fingers and toes. Each nail is convex on its outer surface, concave within, and is implanted by a portion called the **root** into a groove in the skin. The exposed portion is called the **body**, and the distal extremity, the **free edge**. The nail is firmly adherent to the corium, being accurately molded upon its surface; the part beneath the body and root of the nail is called the **nail matrix**, because from it the nail is produced. Under the greater part of the body of the nail, the matrix is thick and raised into a series of longitudinal ridges that are highly vascular, and the color is seen through the transparent tissue. Near the root of the nail, the papillae are smaller, less vascular, and have no regular arrangement, and here the tissue of the nail is not firmly adherent to the connective tissue stratum but only in contact with it; hence this portion is whiter and is called the **lunula** because of its shape.

The cuticle as it passes forward on the dorsal surface of the finger or toe is attached to the surface of the nail a little in advance

**FIG. 14-6.** Median longitudinal section through finger of adult cadaver. The marrow has been removed to show bony trabeculae. 5 ×.

of its root. At the extremity of the finger, it is connected with the undersurface of the nail; both epidermic structures are thus directly continuous with each other. The superficial, horny part of the nail consists of a greatly thickened stratum lucidum; the stratum corneum forms merely the thin cuticular fold (**eponychium**) that overlaps the lunula; and the deeper part consists of the stratum mucosum. The cells in contact with the papillae of the matrix are columnar and arranged perpendicularly to the surface; those that succeed them are round or polygonal, with the more superficial ones becoming broad, thin, flattened, and so closely packed as to make the limits of the cells indistinct. The nails grow in length by the proliferation of the cells of the stratum germinativum at the root of the nail, and they grow in thickness from the part of the stratum germinativum that underlies the lunula.

**HAIR.** Hairs (*pili*) are found on nearly every part of the body's surface, but are absent from the palms of the hands, the soles of the feet, the dorsal surfaces of the terminal phalanges, the glans penis, the inner surface of the prepuce, and the inner surfaces of the labia. They vary much in length, thickness,

and color in different parts of the body and among different races of mankind. In some parts, as in the skin of the eyelids, they are so short that they do not project beyond the follicles containing them; in others, as upon the scalp, they are of considerable length. Some hairs, such as the eyelashes, the pubic hairs, and the whiskers and beard, are remarkable for their thickness. Straight hairs are stronger than curly hairs, and present on transverse section a cylindrical or oval outline; curly hairs, on the other hand, are flat. A hair consists of a **root**, which is the part implanted in the skin, and a **shaft** or **scapus**, which is the portion projecting from the surface.

The **root of the hair** (*radix pili*) ends in an enlargement, the **hair bulb**, which is whiter and softer than the shaft, and is lodged in a follicular involution of the epidermis called the **hair follicle** (Fig. 14-7). The follicle of a very long hair extends into the subcutaneous cellular tissue. The hair follicle commences on the surface of the skin with a funnel-shaped opening and passes inward in an oblique direction for straight hairs or curved for curly hairs; it is dilated at its deep extremity, where it corresponds with the hair

**FIG. 14-7.** Section of human scalp with hairs cut longitudinally. (From Rauber-Kopsch, *Lehrbuch u. Atlas d. Anatomie d. Menschen*, 19th ed., Vol. II, Georg Thieme Verlag, Stuttgart, 1955.)

bulb. Opening into the follicle near its free extremity are the ducts of one or more sebaceous glands. At the bottom of each hair follicle is a small conical, vascular eminence or **papilla**, similar in every respect to those found upon the surface of the skin; it is continuous with the dermic layer of the follicle and supplied with nerve fibrils. The hair follicle consists of two coats—an **outer** or **dermic**, and an **inner** or **epidermic**.

The **outer** or **dermic coat** is formed mainly of fibrous tissue; it is continuous with the dermis, highly vascular, and supplied with numerous minute nervous filaments. It consists of three layers (Fig. 14-8). The most internal is a hyaline basement membrane, which is well marked in the larger hair follicles but not very distinct in the follicles of minute hairs. This membrane is limited to the deeper part of the follicle. Outside this is a compact layer of fibers and spindle-shaped cells arranged circularly around the follicle; this layer extends from the bottom of the follicle as high as the entrance of the ducts of the sebaceous glands. Externally a thick layer of connective tissue is arranged in longitudinal bundles, forming a more open texture and corresponding to the reticular part of the dermis; in this are contained the blood vessels and nerves.

The **inner** or **epidermic coat** adheres closely to the root of the hair and consists of

two strata, named respectively the **outer** and **inner root sheaths**. The outer sheath corresponds with the stratum mucosum of the epidermis and resembles it in the rounded form and soft character of its cells; at the bottom of the hair follicle these cells become continuous with those of the root of the hair. The inner root sheath consists of (1) a delicate cuticle next to the hair, composed of a single layer of imbricated scales with atrophied nuclei; (2) one or two layers of horny, flat nucleated cells, known as **Huxley's layer**<sup>1</sup>; and (3) a single layer of cubical cells with clear, flat nuclei, called **Henle's layer**.<sup>2</sup>

The **hair bulb** is molded over the papilla and composed of polyhedral epithelial cells, which become elongated and spindle-shaped as they pass upward into the root of the hair. Some, however, remain polyhedral in the center. Some of these latter cells contain pigment granules, which are responsible for the color of the hair. It occasionally happens that these pigment granules completely fill the cells in the center of the bulb. This causes the dark tract of pigment, of greater or lesser length, that often is found in the axis of the hair.

<sup>1</sup>Thomas Henry Huxley (1825–1895): An English physiologist and naturalist (London).

<sup>2</sup>Friedrich Gustav Jakob Henle (1809–1885): A German anatomist and histologist (Göttingen).

**FIG. 14-8.** Cross section through hair and root sheath. The red granules in Huxley's layer are keratohyalin. The space between hair and sheath is an artifact. (From Rauber-Kopsch, *Lehrbuch u. Atlas d. Anatomie d. Menschen*, 19th ed., Vol. II, Georg Thieme Verlag, Stuttgart, 1955.)

The **shaft of the hair** (*scapus pili*) consists, from within outward, of three parts: the medulla, the cortex, and the cuticle. The **medulla** is usually wanting in the fine hairs covering the surface of the body, and commonly in those of the head. It is more opaque and deeply colored than the cortex when viewed by transmitted light, but when viewed by reflected light it is white. It is composed of rows of polyhedral cells that contain granules of eleidin and frequently air spaces. The **cortex** constitutes the chief part of the shaft; its cells are elongated and united to form flat fusiform fibers that contain pigment granules in dark hair and air in white hair. The **cuticle** consists of a single layer of flat scales that overlap one another from deep to superficial.

Connected with the hair follicles are minute bundles of involuntary muscular fibers, termed the **arrectores pilorum**. They arise from the superficial layer of the dermis and are inserted into the hair follicle, deep to the entrance of the duct of the sebaceous gland. They are placed on the side toward which the hair slopes, and by their action they diminish the obliquity of the follicle and make the hair stand erect (Fig. 14-7). The sebaceous gland is situated in the angle formed by the arrector muscle with the superficial portion of the hair follicle, and contraction of the muscle thus tends to squeeze the sebaceous secretion from the duct of the gland.

**SEBACEOUS GLANDS.** The sebaceous glands are small, sacculated, glandular organs lodged in the substance of the dermis. They are found in most parts of the skin, but are especially abundant in the scalp and face; they are also numerous around the apertures of the anus, nose, mouth, and external ear, but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which emerges from a cluster of oval or flask-shaped alveoli. The number of alveoli may vary from two to five in number, but in some instances there may be as many as 20. Each alveolus is composed of a transparent basement membrane enclosing epithelial cells. The outer or marginal cells are small, polyhedral, and continuous with the cells lining the duct. The remainder of the alveolus is filled with larger cells that contain lipid, except in the center, where the cells have disintegrated, leaving a cavity filled with their debris and a mass of fatty matter,

**FIG. 14-9.** Sweat gland from the sole of the human foot. (From Rauber-Kopsch, *Lehrbuch u. Atlas d. Anatomie d. Menschen*, 19th ed., Vol. II, Georg Thieme Verlag, Stuttgart, 1955.)

which constitute the **sebum cutaneum**. The ducts open most frequently into the hair follicles, but occasionally upon the general surface, as in the labia minora and the free margin of the lips. On the nose and face the glands are large, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The tarsal glands of the eyelids are elongated sebaceous glands with numerous lateral diverticula.

**SUDORIFEROUS GLANDS.** The sudoriferous or sweat glands (*glandulae sudoriferae*) (Fig. 14-9) are found in almost every part of the skin. Each consists of a single tube, the deep part of which is irregularly coiled into an oval or spherical ball, named the **body** of the gland, while the superficial part, or **duct**, traverses the dermis and cuticle and opens on the surface of the skin by a funnel-shaped aperture. In the superficial layers of the dermis the duct is straight, but in the deeper layers it is convoluted or even twisted. Where the epidermis is thick, as in the palms of the hands and soles of the feet, the part of the duct that passes through it is spirally coiled. The size of the glands varies. They are especially large in those regions where the amount of perspiration is great, as in the axillae, where they form a thin, mammillated layer of a reddish color, which corresponds exactly to the situation of the hair in this region; the glands are also large in the groin.

The number of glands varies. They are plentiful on the palms of the hands and on the soles of the feet, where the orifices of the ducts are exceedingly regular and open on the curved ridges. They are least numerous in the neck and back. The palm has about 370 glands per square centimeter; the back of the hand, about 200; the forehead, 175; the breast, abdomen, and forearm, 155, and the

leg and back, 60 to 80. It has been estimated that the total number is about 2,000,000. The following shows the average number of sweat glands per square centimeter of skin on the fingers in various races (Clark and Llamon, 1917):

American (white) . . . . .	558.2
American (Negro) . . . . .	597.2
Filipino . . . . .	653.6
Moro . . . . .	684.4
Negrito (adult) . . . . .	709.2
Hindu . . . . .	738.2
Negrito (youth) . . . . .	950.0

Sweat glands are absent in the deeper portion of the external auditory meatus, the prepuce, and the glans penis.

The tube, both in the body of the gland and in the duct, consists of two layers—an outer layer of fine **areolar tissue** and an inner layer of **epithelium**. The outer layer is thin and continuous with the superficial stratum of the dermis. In the body of the gland, the epithelium consists of a single layer of cubical cells, between the deep ends of which the basement membrane is a layer of longitudinally or obliquely arranged nonstriated muscular fibers. The ducts are destitute of muscular fibers and are composed of a basement membrane lined by two or three layers of polyhedral cells; the lumen of the duct is coated by a thin cuticle. When the epidermis is carefully removed from the surface of the dermis, the ducts may be pulled out from the dermis in the form of short, thread-like processes. The ceruminous glands of the external acoustic meatus, the ciliary glands at the margins of the eyelids, the circumanal glands and probably the mammary glands are modified sudoriferous glands. The average quantity of sweat secreted in 24 hours varies from 700 to 900 gm.

## The Respiratory System

Respiration, or exchange of gaseous substance between the air and the blood stream, is brought about in the respiratory system (respiratory apparatus): the nose, nasal passages, nasopharynx, larynx, trachea, bronchi, and lungs. The pleura, pleural cavities, and the topography of other structures in the thorax are also described in this chapter. The muscular actions associated with respiration are discussed with the description of the diaphragm in Chapter 6.

### Development

The development of the nose is described in Chapter 2, Embryology.

The primordium of the principal respiratory organs appears as a median longitudinal groove in the ventral wall of the pharynx in an embryo of the third week (3 to 4 mm). The groove deepens and its lips fuse to form the **laryngotracheal tube** (Fig. 15-1), the cranial end of which opens into the pharynx by a slit-like aperture formed by the persistent

ventral part of the groove. The tube is lined by endoderm, from which the epithelial lining of the respiratory tract is developed. The cranial part of the tube becomes the larynx, its next succeeding part the trachea, and from its caudal end two lateral outgrowths arise, the right and left **lung buds**, from which the bronchi and lungs develop.

The first rudiment of the larynx consists of two **arytenoid swellings**, which appear on either side of the cranial end of the laryngotracheal groove and are continuous ventrally with a transverse ridge (**furcula of His**<sup>1</sup>) that lies between the ventral ends of the third branchial arches and from which the epiglottis is subsequently developed (Figs. 16-4; 16-5). After the separation of the trachea from the esophagus the arytenoid swellings come into contact with each other and with the back of the epiglottis, and the entrance to the larynx assumes the form of a T-shaped cleft. The margins of the cleft adhere to each other and the laryngeal entrance is occluded for a time.

The mesodermal wall of the tube condenses to form the cartilages of the larynx and trachea. The arytenoid swellings differentiate into the arytenoid and corniculate cartilages, and the folds joining them to the epiglottis form the aryepiglottic folds, in which the cuneiform cartilages develop as derivatives of the epiglottis. The thyroid cartilage appears as two lateral plates, each chondrified from two centers and united in the ventral midline by membrane in which an additional center of chondrification develops. The cricoid cartilage arises from two cartilaginous centers that soon unite ventrally and gradually grow around to fuse on the dorsal aspect of the tube.

The right and left lung buds grow out dorsal to the common cardinal veins and are at first symmetrical, but their ends soon become lobulated, three lobules appearing on the right, and two on the left. These subdivisions are the early indications of the corresponding lobes of the lungs (Figs. 15-2; 15-3). The buds undergo further subdivision and ramification, and ultimately end in minute expanded extremities—the infundibula of the lung. After the sixth month the air sacs begin to appear on the infundibula in the form of minute pouches.

<sup>1</sup>Wilhelm His (1831-1904): A German anatomist and physiologist (Basel and Leipzig).

**Fig. 15-1.** The head and neck of a 32-day-old human embryo seen from the ventral surface. The floor of the mouth and pharynx has been removed. (His.)

During the course of their development the lungs migrate in a caudal direction, so that by the time of birth the bifurcation of the trachea is opposite the fourth thoracic vertebra. As the lungs grow, they project into the part of the celom that will ultimately form the pleural cavities, and the superficial layer of the mesoderm enveloping the lung rudiment expands on the growing lung and is converted into the pulmonary pleura.

The pulmonary arteries are derived from the sixth aortic arches (Figs. 8-6 to 8-9).

## Upper Respiratory Tract

### NOSE

#### External Nose

The external nose is shaped like a pyramid, its free angle termed the **apex**. The two elliptical orifices, the **nares**, are separated from each other by a median septum, the **columna**. The interior surface of the anterior

**nares or nostrils** is provided with stiff hairs, or **vibrissae**, which arrest the passage of foreign substances carried with the current of air intended for respiration. The lateral surfaces of the nose form, by their union in the midline, the **dorsum nasi**, the direction of which varies considerably in different individuals. The upper part of the dorsum is supported by the nasal bones and is named the **bridge**. The lateral surface ends below in rounded eminences, the **alae nasi**.

**STRUCTURE.** The framework of the external nose is composed of bones and cartilages; it is covered by the integument and is lined by mucous membrane.

**Bones and Cartilage.** The **bony framework** occupies the upper part of the organ; it consists of the nasal bones and the frontal processes of the maxillae.

The **cartilaginous framework** consists of

**Fig. 15-2.** Lung buds from a human embryo of about four weeks, showing commencing lobulations. (His.)

**Fig. 15-3.** Lungs of a human embryo more advanced in development. (His.)

five large pieces: the **septal cartilage**, the two **lateral** and the two **greater alar cartilages**, and several smaller pieces, the **lesser alar cartilages** (Figs. 15-4 to 15-7). The various cartilages are connected to each other and to the bones by a tough fibrous membrane.

The **septal cartilage** is thicker at its margins than at its center and separates the nasal cavities. Its anterior margin is connected with the nasal bones, and is continuous with the anterior margins of the lateral cartilages. Inferiorly, it is connected to the medial crura of the greater alar cartilages by fibrous tissue. Its posterior margin is connected with the perpendicular plate of the ethmoid; its inferior margin, with the vomer and the palatine processes of the maxillae.

The septal cartilage may be prolonged posteriorly (especially in children) for some distance between the vomer and perpendicular plate of the ethmoid as a narrow process, the **sphenoidal process**. The septal cartilage does not reach as far as the lowest part of the nasal septum. This is formed by the medial crura of the greater alar cartilages.

The **lateral cartilage** (upper lateral cartilage) is situated below the inferior margin of the nasal bone; it is flat and triangular. Its anterior margin is thicker than the posterior, and is continuous above with the cartilage of the septum, but separated from it below by a narrow fissure. Its superior margin is attached to the nasal bone and the frontal process of the maxilla; its inferior margin is connected by fibrous tissue with the greater alar cartilage.

The **greater alar cartilage** (lower lateral cartilage) is a thin, flexible plate situated

FIG. 15-5. Cartilages of the nose. Inferior view.

immediately below the lateral cartilage and bent upon itself in such a manner that it forms the medial and lateral walls of the naris of its own side. The portion that forms the **medial wall** is loosely connected with the corresponding portion of the opposite cartilage, the two forming, together with the thickened integument and subjacent tissue, the **septum mobile nasi**. The part that forms the **lateral wall** is curved to correspond with the ala of the nose. It is oval, flat, and narrow posteriorly where it is connected with the frontal process of the maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates, the **lesser alar cartilages** (sesamoid cartilages). Superiorly, the greater alar cartilage is connected by fibrous tissue to the lateral cartilage and anterior part of the cartilage of the septum; inferiorly, it falls short of the margin of the naris, the ala being completed by fatty and fibrous tissue covered by skin. Anteriorly, the greater alar cartilages are separated by a notch that corresponds with the apex of the nose.

FIG. 15-4. Cartilages of the nose. Side view.

FIG. 15-6. Bones and cartilages of septum of nose. Right side.

Fig. 15-7. Cartilages of the nose. Anterior view.

**Muscles.** The muscles acting on the external nose are described in Chapter 6.

**Integument.** The integument of the dorsum and sides of the nose is thin and loosely connected with the subjacent parts, but over the tip and alae it is thicker and more firmly adherent, and is furnished with a large number of sebaceous follicles, the orifices of which are usually quite distinct.

**Vessels and Nerves.** The **arteries** of the external nose are the alar and septal branches of the facial artery, which supply the alae and septum. The dorsum and sides are supplied from the dorsal nasal branch of the ophthalmic artery and the infraorbital branch of the maxillary artery. The **veins** end in the facial and ophthalmic veins.

The **nerves** for the muscles of the nose are derived from the facial nerve. The skin receives branches from the infratrochlear and nasociliary branches of the ophthalmic nerve and from the infraorbital branch of the maxillary nerve.

### Nasal Cavity

The **nasal cavity** is divided by the median septum into two symmetrical and approximately equal chambers, the **nasal fossae**. They have their external openings through the nostrils or nares, and they open into the nasopharynx through the choanae. The nares are oval apertures measuring about 1.5 cm anteroposteriorly and 1 cm transversely. The choanae are two oval openings

measuring approximately 2.5 cm vertically and 1.5 cm transversely.

The bony boundaries of the nasal cavity are described in Chapter 4, Osteology.

Inside the aperture of the nostril is a slight dilatation, the **vestibule**, which is bounded laterally by the ala and lateral crus of the greater alar cartilage and medially by the medial crus of the same cartilage. It is lined by skin containing hairs and sebaceous glands, and it extends as a small recess toward the apex of the nose. Each nasal fossa is divided into two parts: an **olfactory region**, consisting of the superior nasal concha and the opposed part of the septum, and a **respiratory region**, which comprises the rest of the cavity.

**LATERAL WALL** (Figs. 15-8; 15-9). On the lateral wall are the **superior, middle, and inferior nasal conchae**, overhanging the corresponding nasal passages or **meatuses**. Above the superior concha is a narrow recess, the **sphenoethmoidal recess**, into which the sphenoidal sinus opens. The **superior meatus** is a short oblique passage that extends about half way along the superior border of the middle concha; the posterior ethmoidal cells open into the anterior part of this meatus. The **middle meatus** is continued anteriorly into a shallow depression situated above the vestibule and named the **atrium** of the middle meatus. The lateral wall of this meatus is fully displayed only by raising or removing the middle concha. On it is a rounded elevation, the **bullae ethmoidalis**, and anterior and inferior to this is a curved cleft, the **hiatus semilunaris**.

The **bullae ethmoidalis** (Fig. 15-9) is caused by the bulging of the middle ethmoidal cells, which open on or immediately above it, and the size of the bulla varies with that of its contained cells.

The **hiatus semilunaris** is the narrow curved opening into a deep pocket, the **infundibulum**. It is bounded inferiorly by the sharp concave margin of the **uncinate process** of the ethmoid bone, and superiorly, by the bulla ethmoidalis. The anterior ethmoidal cells open into the anterior part of the infundibulum. In slightly over 50% of subjects, the infundibulum is directly continuous with the **frontonasal duct** or passage leading from the frontal air sinus. When the anterior end of the uncinate process fuses with the anterior part of the bulla, this continuity is interrupted, and the frontonasal

FIG. 15-8. Lateral wall of nasal cavity.

FIG. 15-9. Lateral wall of nasal cavity; the three nasal conchae have been removed.

duct then opens directly into the anterior end of the middle meatus.

In the bottom of the infundibulum, below the bulla ethmoidalis and partly hidden by the inferior end of the uncinate process, is the **ostium maxillare**, or opening from the maxillary sinus. This opening is placed near the roof of the sinus. An **accessory** opening from the sinus is frequently present below the posterior end of the middle nasal concha. The **inferior meatus** is inferior and lateral to the inferior nasal concha; the nasolacrimal duct opens into this meatus under cover of the anterior part of the concha.

**MEDIAL WALL** (Fig. 15-6). The medial wall or septum is frequently deflected from the median plane, thus lessening the size of one nasal fossa and increasing that of the other; ridges or spurs of bone growing into one or the other fossa from the septum are also sometimes present. Immediately over the incisive canal at the inferior edge of the cartilage of the septum is a depression, the **nasopalatine recess**. In the septum close to this recess a minute orifice may be discerned; it leads posteriorly into a blind pouch, the rudimentary **vomeronasal organ of Jacobson**,<sup>1</sup> which is supported by a strip of cartilage, the **vomeronasal cartilage**. This organ is well developed in many of the lower animals, where it apparently plays a part in the sense of smell, since it is supplied by twigs of the olfactory nerve and is lined by epithelium similar to that in the olfactory region of the nose.

**ROOF.** The roof of the nasal cavity is narrow from side to side, except at its posterior part, and may be divided into sphenoidal, ethmoidal, and frontonasal parts, after the bones that form it.

**FLOOR.** The floor is concave from side to side. Its anterior three-fourths are formed by the palatine process of the maxilla; its posterior fourth is formed by the horizontal process of the palatine bone.

**MUCOUS MEMBRANE.** The nasal mucous membrane lines the nasal cavity and adheres intimately to the periosteum or perichondrium. It is continuous with the skin through the nares, and with the mucous membrane of the nasal part of the pharynx through the choanae. From the nasal fossa its continuity with the conjunctiva may be traced through the nasolacrimal and lacrimal ducts; it is

continuous with the frontal, ethmoidal, sphenoidal, and maxillary sinuses through the several openings in the meatuses. Continuity with the middle ear is established with the nasopharynx through the auditory tube. The mucous membrane is thickest and most vascular over the nasal conchae. It is also thick over the septum, but very thin in the meatuses, on the floor of the nasal cavity, and in the various sinuses.

Owing to the thickness of the greater part of this membrane, the nasal cavities are much narrower and the middle and inferior nasal conchae appear larger and more prominent than in the skeleton; the various apertures communicating with the meatuses also are considerably narrowed.

**Structure of the Mucous Membrane.** The mucous membrane covering the **respiratory portion** of the nasal cavity has a pseudostratified, ciliated, columnar epithelium, liberally interspersed with goblet cells. Beneath the basement membrane of the epithelium, the areolar connective tissue is infiltrated with lymphocytes, which may be so numerous that they form a diffuse lymphoid tissue. The lamina propria is composed of a layer of glands toward the surface and a layer of blood vessels next to the periosteum. The glands may be large or small and contain either mucous or serous alveoli. They have individual openings on the surface, and their secretion forms a protective layer over the membrane which serves to warm and moisten the inspired air. In the deeper layers of the lamina propria, especially over the conchae, the dilated veins and blood spaces form a rich plexus that bears a superficial resemblance to erectile tissue; these areas easily become engorged as the result of irritation or inflammation, causing the membrane to swell and encroach upon the lumen of the meatuses, and even occlude the ostia of the sinuses.

The mucous membrane of the paranasal sinuses is columnar ciliated, similar to that of the nasal fossae, but is much thinner and for the most part lacking in glands in the lamina propria.

The **olfactory portion** of the mucous membrane of the nasal cavity is described at the beginning of Chapter 13.

**Vessels and Nerves.** The **arteries** of the nasal cavities are the anterior and posterior ethmoidal branches of the ophthalmic artery, which supply the ethmoidal cells, frontal sinuses, and roof of the

<sup>1</sup>Ludwig Levin Jacobson (1783-1843): A Danish anatomist and physician (Copenhagen).

**Fig. 15-10.** Transverse section through the anterior part of the head at a level just inferior to the apex of the dens (odontoid process). Inferior view.

nose; the sphenopalatine branch of the maxillary artery, which supplies the mucous membrane covering the conchae, the meatuses, and septum; the septal ramus of the superior labial branch of the facial artery; the infraorbital and alveolar branches of the maxillary artery, which supply the lining membrane of the maxillary sinus; and the pharyngeal branch of the maxillary artery, which is distributed to the sphenoidal sinus. The ramifications of these vessels form a close plexiform network beneath and in the substance of the mucous membrane.

Some veins open into the sphenopalatine vein; others join the facial vein. Some accompany the ethmoidal arteries and end in the ophthalmic veins, and a few communicate with the veins on the orbital surface of the frontal lobe of the brain through the foramina in the cribriform plate of the ethmoid bone. When the foramen cecum is patent, it transmits a vein to the superior sagittal sinus.

The **lymphatics** are described in Chapter 10.

The **nerves** of ordinary sensation are: the nasociliary branch of the ophthalmic nerve, filaments from the anterior alveolar branch of the maxillary nerve, the nerve of the pterygoid canal, the nasopalatine nerve, the anterior palatine nerve, and nasal branches of the pterygopalatine nerve.

The nasociliary branch of the ophthalmic nerve distributes filaments to the anterior part of the septum and lateral wall of the nasal cavity. Filaments from the anterior alveolar nerve supply the inferior meatus and inferior concha. The nerve of the ptery-

goid canal supplies the upper and back part of the septum and superior concha; the upper nasal branches from the pterygopalatine nerve have a similar distribution. The nasopalatine nerve supplies the middle of the septum. The anterior palatine nerve supplies the lower nasal branches to the middle and inferior conchae.

The **olfactory nerves**, the nerves of the special sense of smell, are a number of fine filaments distributed to the mucous membrane of the olfactory region. Their fibers arise from the bipolar olfactory cells and lack medullary sheaths. They unite into fasciculi that form a plexus beneath the mucous membrane and then ascend in grooves or canals in the ethmoid bone. They pass into the skull through the foramina in the cribriform plate of the ethmoid and enter the olfactory bulb, in which they ramify and form synapses with the dendrites of the mitral cells (see Chapter 13).

### **Accessory Sinuses of the Nose**

The **accessory sinuses** or **air cells of the nose** (paranasal sinuses) (Figs. 15-9 to 15-12) are the **frontal, ethmoidal, sphenoidal, and maxillary**. They vary in size and form in different individuals and are lined by ciliated mucous membrane directly continuous with that of the nasal cavity.

**FRONTAL SINUSES.** The frontal sinuses, sit-

FIG. 15-11. Coronal section of nasal cavities.

uated behind the superciliary arches, are rarely symmetrical, and the septum between them frequently deviates to one side or the other of the midline. Their average measurements are: height, 3 cm; breadth, 2.5 cm; depth, 2.5 cm. A large frontal sinus may extend out over most of the orbit. Each opens into the anterior part of the corresponding middle meatus of the nose through the frontonasal duct, which enters the anterior part of the middle meatus. Absent at birth, the frontal sinuses are generally fairly well developed between the seventh and eighth years, but reach their full size only after puberty.

**ETHMOIDAL AIR CELLS.** The ethmoidal air cells consist of numerous small, thin-walled cavities occupying the ethmoidal labyrinth and completed by the frontal, maxillary, lacrimal, sphenoidal, and palatine bones. They lie between the upper parts of the nasal cavities and the orbits, and are separated from these cavities by thin bony laminae. On either side they are arranged in three groups: **anterior, middle, and posterior**. The anterior and middle groups open into the middle meatus of the nose, the former by way of the infundibulum, the latter on or above the

bullae ethmoidalis. The posterior cells open into the superior meatus under cover of the superior nasal concha; sometimes one or more open into the sphenoidal sinus. The ethmoidal cells begin to develop after fetal life.

**SPHENOIDAL SINUSES.** The sphenoidal sinuses (Fig. 15-9), contained within the body of the sphenoid, vary in size and shape, and owing to the lateral displacement of the intervening septum, they are rarely symmetrical. Their average measurements are: vertical height, 2.2 cm; transverse breadth, 2 cm; depth 2.2 cm. When exceptionally large, they may extend into the roots of the pterygoid processes or great wings, and may invade the basilar part of the occipital bone. Each sinus communicates with the sphenoidal recess by means of an ostium in the upper part of its anterior wall. The sphenoidal sinuses are present as minute cavities at birth, but their main development takes place after puberty.

**MAXILLARY SINUS.** The maxillary sinus (antrum of Highmore<sup>1</sup>), the largest of the

<sup>1</sup>Nathaniel Highmore (1613-1685): An English physician (Sherborne).

**Fig. 15-12.** Radiograph of adult skull, frontal view, showing the frontal sinus (F), the ethmoid air cells (E), and the maxillary sinus (M). (From Juhl, J.H., *Essentials of Roentgen Interpretation*, 4th ed., Harper and Row Publishers, Hagerstown, Md., 1981.)

accessory sinuses of the nose, is a pyramidal cavity in the body of the maxilla. Its base is formed by the lateral wall of the nasal cavity, and its apex extends into the zygomatic process. Its roof or orbital wall is frequently ridged by the bony wall of the infraorbital canal; its floor is formed by the alveolar process and is usually 1 to 10 mm below the level of the floor of the nose. Projecting into the floor are several conical elevations corresponding with the roots of the first and second molar teeth, and in some cases the floor is perforated by one or more of these roots. The size of the sinus varies in different skulls and even on the two sides of the same skull. The adult capacity varies from 9.5 cc to 20 cc (average about 14.75 cc). The measurements of an average-sized sinus are: vertical height opposite the first molar tooth, 3.75 cm; transverse breadth, 2.5 cm; anteroposterior depth, 3 cm. In the superior part of its medial wall is an ostium through which it communicates with the lower part of the infundibulum; a second or accessory orifice is frequently

present in the middle meatus posterior to the first. The maxillary sinus appears as a shallow groove on the medial surface of the bone about the fourth month of fetal life, but does not reach its full size until after the second dentition.

### LARYNX

The larynx or organ of voice is the part of the air passage that connects the pharynx with the trachea. It produces a considerable projection in the midline of the neck called the Adam's apple. It forms the inferior part of the anterior wall of the pharynx, and is covered by the mucous lining of that cavity. Its vertical extent corresponds to the fourth, fifth, and sixth cervical vertebrae, but it is placed somewhat higher in the female and also during childhood; on either side of it lie the great vessels of the neck. The average measurements of the adult larynx in both males and females appear on page 1366.

	Males (mm)	Females (mm)
Length . . . . .	44	36
Transverse diameter . . . . .	43	41
Anteroposterior diameter . . . . .	36	26
Circumference . . . . .	136	112

Until puberty the larynx of the male differs little in size from that of the female. In the female its increase after puberty is only slight; in the male it undergoes considerable increase; all the cartilages are enlarged and the thyroid cartilage becomes prominent in the midline of the neck, while the length of the rima glottidis is nearly doubled.

The larynx is broad above, where it presents the form of a triangular box flattened dorsally and at the sides, and it is bounded ventrally by a prominent vertical ridge. Caudally, it is narrow and cylindrical. It is composed of cartilages, which are connected together by ligaments and moved by numerous muscles. It is lined by mucous membrane continuous with that of the pharynx and the trachea.

### *Cartilages of the Larynx*

There are nine cartilages of the larynx (Fig. 15-13), three single and three paired, as follows:

Thyroid  
Cricoid  
Arytenoid (two)  
Corniculate (two)  
Cuneiform (two)  
Epiglottis

**THYROID CARTILAGE.** The thyroid cartilage (Fig. 15-13) is the largest cartilage of the larynx. It consists of two laminae, the anterior borders of which are fused with each other at an acute angle in the midline of the neck; these form a subcutaneous projection named the **laryngeal prominence** (Adam's apple). This prominence is most distinct at its cranial part and is larger in the male than in the female. Immediately above it, the laminae are separated by a V-shaped notch, the **superior thyroid notch**. The laminae are irregularly quadrilateral in shape, and their posterior angles are prolonged into processes termed the **superior** and **inferior cornua**.

On the outer surface of each lamina an **oblique line** runs caudalward and ventral-

Fig. 15-13. The cartilages of the larynx. Posterior view.

ward from the superior thyroid tubercle, situated near the root of the superior cornu, to the inferior thyroid tubercle on the caudal border. This line gives attachment to the sternothyroid, thyrohyoid, and the inferior pharyngeal constrictor. The inner surface is smooth; cranially and dorsally it is slightly concave and covered by mucous membrane. Ventrally, in the angle formed by the junction of the laminae, are attached the stem of the epiglottis, the ventricular and vocal ligaments, the thyroarytenoid, thyroepiglotticus, and vocalis muscles, and the thyroepiglottic ligament.

The cranial border is concave dorsally and convex ventrally; it gives attachment to the corresponding half of the thyrohyoid

membrane. The *caudal border* is concave dorsally and nearly straight ventrally, the two parts being separated by the inferior thyroid tubercle. A small part of it in and near the midline is connected to the cricoid cartilage by the middle cricothyroid ligament. The *dorsal border*, thick and rounded, receives the insertions of the stylopharyngeus and palatopharyngeus. It ends cranially, in the superior cornu, and caudally, in the inferior cornu. The **superior cornu** is long and narrow, directed cranialward, and ends in a conical extremity, which gives attachment to the lateral thyrohyoid ligament. The **inferior cornu** is short and thick; it is directed caudalward, with a slight inclination, and presents, on the medial side of its tip, a small oval articular facet for articulation with the side of the cricoid cartilage.

During infancy, the laminae of the thyroid cartilage are joined to each other by a narrow, lozenge-shaped strip named the **intra-thyroid cartilage**. This strip extends from the cranial to the caudal border of the cartilage in the midline, and is distinguished from the laminae by being more transparent and more flexible.

**CRICOID CARTILAGE.** The cricoid cartilage (Fig. 15-13) is smaller but thicker and stronger than the thyroid, and forms the caudal and dorsal parts of the wall of the larynx. It consists of two parts: a **posterior quadrate lamina** and a narrow **anterior arch**, one-fourth or one-fifth of the depth of the lamina.

The **lamina** of the cricoid cartilage is deep and broad and measures about 2 or 3 cm craniocaudally. On its dorsal surface, in the midline, is a vertical ridge, to the caudal part of which are attached the longitudinal fibers of the esophagus, and on either side of this ridge is a broad depression for the posterior cricoarytenoid.

The **arch** is narrow, convex, and measures vertically from 5 to 7 mm; it affords attachment externally, ventrally, and at the sides to the cricothyroid muscle, and dorsally, to part of the inferior constrictor of the pharynx.

On either side, at the junction of the lamina with the arch, is a small round articular surface for articulation with the inferior cornu of the thyroid cartilage.

The *caudal border* of the cricoid cartilage is horizontal and connected to the highest ring of the trachea by the cricotracheal ligament. The *cranial border* runs obliquely

cranialward and dorsalward, owing to the great depth of the lamina. It gives attachment, ventrally, to the middle cricothyroid ligament and at the side, to the conus elasticus and the lateral cricoarytenoids. Dorsally, it has a shallow notch in the middle, and on either side of this a smooth, oval convex surface for articulation with the base of an arytenoid cartilage. The inner surface of the cricoid cartilage is smooth and lined by mucous membrane.

**ARYTENOID CARTILAGE.** The arytenoid cartilages (Fig. 15-13) are two in number, situated at the cranial border of the lamina of the cricoid cartilage, at the dorsum of the larynx. Each is pyramidal and has three surfaces, a base, and an apex.

The *dorsal surface* is triangular, smooth, concave, and gives attachment to the oblique and transverse arytenoid. The *ventrolateral surface* is somewhat convex and rough. On it, near the apex of the cartilage, is a rounded elevation (**colliculus**) from which a ridge (**crista arcuata**) curves at first dorsalward and then caudalward and ventralward to the vocal process. The caudal part of this crest intervenes between two depressions or **foveae**: an upper triangular depression and a lower oblong depression. The latter gives attachment to the vocalis muscle. The *medial surface* is narrow, smooth, and flat. It is covered by mucous membrane and forms the lateral boundary of the intercartilaginous part of the rima glottidis.

The **base** of each cartilage is broad, and has a concave smooth surface for articulation with the cricoid cartilage. Its lateral angle is short, round, and prominent; it projects dorsalward, and is termed the **muscular process**. It receives the insertion of the posterior cricoarytenoid dorsally and the lateral cricoarytenoid ventrally. Its anterior angle, also prominent but more pointed, projects horizontally ventralward; it gives attachment to the vocal ligament and is called the **vocal process** (Fig. 15-16).

The **apex** of each cartilage is pointed, curved dorsalward and medialward, and surmounted by a small conical, cartilaginous nodule, the **corniculate cartilage**.

**CORNICULATE CARTILAGE.** The corniculate cartilages (*cartilages of Santorini*<sup>1</sup>) are two small conical nodules consisting of yellow

<sup>1</sup>Giovanni Domenico Santorini (1681-1737): An Italian anatomist (Venice).

elastic cartilage, which articulate with the summits of the arytenoid cartilages and serve to prolong them dorsalward and medialward. They are situated in the posterior parts of the aryepiglottic folds of mucous membrane, and they are sometimes fused with the arytenoid cartilages.

**CUNEIFORM CARTILAGE.** The cuneiform cartilages (*cartilages of Wrisberg*<sup>2</sup>) are two small, elongated pieces of yellow elastic cartilage, placed one on either side, in the aryepiglottic fold, where they give rise to small

whitish elevations on the surface of the mucous membrane, just ventral to the arytenoid cartilages.

**EPIGLOTTIS.** The epiglottis (Fig. 15-13) is a thin lamella of yellow elastic cartilage, shaped like a leaf. It projects obliquely upward behind the root of the tongue and ventral to the entrance of the larynx. The free extremity is broad and round; the attached part or stem is long, narrow, and connected by the **thyroepiglottic ligament** to the angle formed by the two laminae of the thyroid cartilage, a short distance caudal to the superior thyroid notch. The caudal part of its anterior surface is connected to the cranial

<sup>2</sup>Heinrich August Wrisberg (1739-1808): A German anatomist (Göttingen).

FIG. 15-14. The ligaments of the larynx. Anterolateral view.

border of the body of the hyoid bone by an elastic ligamentous band, the **hyoepiglottic ligament**.

The anterior or *lingual surface* is curved ventralward and is covered on its cranial, free part by mucous membrane, which is reflected onto the sides and root of the tongue, forming a median and two lateral **glossoepiglottic folds**. The lateral folds are partly attached to the wall of the pharynx. The depressions between the epiglottis and the root of the tongue, on either side of the median fold, are named the **valleculae** (Fig. 15-18). The caudal part of the anterior surface lies dorsal to the hyoid bone, the hyothyroid membrane, and the upper part of the thyroid cartilage, but is separated from these structures by a mass of fatty tissue.

The posterior or *laryngeal surface* is smooth, concave from side to side, and concavoconvex vertically; its caudal part projects dorsalward as an elevation, the **tubercle** or **cushion**. The surface of the cartilage is indented by a number of small pits in which mucous glands are lodged. To its sides the aryepiglottic folds are attached.

**STRUCTURE.** The corniculate and cuneiform cartilages, the epiglottis, and the apices of the arytenoids at first consist of hyaline cartilage, but later elastic fibers are deposited in the matrix, converting them into yellow elastic cartilage that shows little tendency to calcification. The thyroid, cricoid, and the greater part of the arytenoids consist of hyaline cartilage and become more or less ossified as age advances. Ossification commences about the twenty-fifth year in the thyroid cartilage and somewhat later in the cricoid and arytenoids; by the sixty-fifth year these cartilages may be completely converted into bone.

### Ligaments

The ligaments of the larynx (Figs. 15-14; 15-15) are **extrinsic** (those that connect the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea) and **intrinsic** (those that connect the several cartilages of the larynx to each other).

**EXTRINSIC LIGAMENTS.** The ligaments that connect the thyroid cartilage with the hyoid bone are the thyrohyoid membrane and a middle and two lateral thyrohyoid ligaments.

The **thyrohyoid membrane** (*hyothyroid membrane*) is a broad, fibroelastic layer attached to the cranial border of the thyroid cartilage and to the front of its superior cornu, and to the cranial margin of the dorsal surface of the body and greater cornua of the hyoid bone. It thus passes dorsal to the posterior surface of the body of the hyoid, and is separated from it by a bursa that facilitates the upward movement of the larynx during deglutition. Its middle thicker part is termed the **middle thyrohyoid ligament** (*middle hyothyroid ligament*); its lateral thinner portions are pierced by the superior laryngeal vessels and the internal branch of the superior laryngeal nerve. Its anterior surface is in relation with the thyrohyoid, sternohyoid, and omohyoid muscles, and with the body of the hyoid bone.

The **thyrohyoid ligament** (*lateral hyothyroid ligament*) is a round elastic cord that forms the posterior border of the thyrohyoid membrane and passes between the tip of the superior cornu of the thyroid cartilage and the extremity of the greater cornu of the hyoid bone. A small cartilaginous nodule (*cartilago triticea*), sometimes bony, is frequently found in it.

The epiglottis is connected with the hyoid bone by an elastic band, the **hyoepiglottic ligament**, which extends from the anterior surface of the epiglottis to the upper border of the body of the hyoid bone. The glossoepiglottic folds of mucous membrane may also be considered extrinsic ligaments of the epiglottis.

The **cricotracheal ligament** connects the cricoid cartilage with the first ring of the trachea. It resembles the fibrous membrane that connects the cartilaginous rings of the trachea to each other.

**INTRINSIC LIGAMENTS.** Beneath the mucous membrane of the larynx is a broad sheet of fibrous tissue that contains many elastic fibers and is termed the **elastic membrane of the larynx**. It is subdivided on either side by the interval between the ventricular and vocal ligaments. The cranial portion extends between the arytenoid cartilage and the epiglottis and is often poorly defined; the caudal part is a well-marked membrane that forms, with its fellow of the opposite side, the *conus elasticus*, which connects the thyroid, cricoid, and arytenoid cartilages to one another.

**FIG. 15-15.** The ligaments of the larynx viewed from the posterior aspect. Note that the right half of the thyrohyoid membrane has been removed to show the contours of the thyroid cartilage, the epiglottis, and the hyoid bone.

The **conus elasticus** (cricothyroid membrane) is composed mainly of yellow elastic tissue. It consists of an anterior and two lateral portions. The **anterior part** or **middle cricothyroid ligament** (*ligamentum cricothyroideum medium*; central part of cricothyroid membrane) is thick, strong, and connects the ventral parts of the contiguous margins of the thyroid and cricoid cartilages. It is overlapped on either side by the crico-

thyroid muscles, but between these it is subcutaneous; it is crossed horizontally by a small anastomotic arterial arch formed by the junction of the two cricothyroid arteries, branches of which pierce it. The **lateral portions** are thinner and lie close under the mucous membrane of the larynx; they extend from the superior border of the cricoid cartilage to the inferior margin of the vocal ligaments, with which they are continuous.

These ligaments may, therefore, be regarded as the free borders of the lateral portions of the conus elasticus, and they extend from the vocal processes of the arytenoid cartilages to the angle of the thyroid cartilage about midway between its cranial and caudal borders.

An **articular capsule**, strengthened posteriorly by a well-marked fibrous band, encloses the articulation of the inferior cornu of the thyroid with the cricoid cartilage on either side.

Each arytenoid cartilage is connected to the cricoid by a capsule and a posterior cricoarytenoid ligament. The **capsule** is thin and loose and is attached to the margins of the articular surfaces. The **posterior cricoarytenoid ligament** extends from the cricoid to the medial and dorsal part of the base of the arytenoid.

The **thyroepiglottic ligament** is a long, slender, elastic cord that connects the stem of the epiglottis with the angle of the thyroid cartilage immediately beneath the superior thyroid notch and cranial to the attachment of the ventricular ligaments.

**MOVEMENTS.** The articulation between the inferior cornu of the thyroid cartilage and the cricoid cartilage on either side is diarthrodial and permits rotatory and gliding movements. During the rotatory movement, the cricoid cartilage rotates upon the inferior cornua of the thyroid cartilage around an axis that passes transversely through both joints. The gliding movement consists of a limited shifting of the cricoid on the thyroid in different directions.

The articulation between the arytenoid cartilages and the cricoid is also diarthrodial and permits two varieties of movement: one is rotation of the arytenoid on a vertical axis, whereby the vocal process is moved lateralward or medialward and the rima glottidis is increased or diminished; the other is a gliding movement, which allows the arytenoid cartilages to approach or recede from each other. From the direction and slope of the articular surfaces, lateral gliding is accompanied by a forward and downward movement. The two movements of gliding and rotation are associated, the medial gliding being connected with the medialward rotation, and the lateral gliding with lateralward rotation. The posterior cricoarytenoid ligaments limit the forward movement of the arytenoid cartilages on the cricoid.

### *Interior of the Larynx*

The **cavity of the larynx** extends from the laryngeal entrance to the caudal border of the cricoid cartilage, where it is continuous with that of the trachea. It is divided into

two parts by the projection of the vocal folds, between which is a narrow triangular fissure or opening, the **rima glottidis**. The portion of the cavity of the larynx above the vocal folds is called the **vestibule**. It is wide and triangular; about the center of its base or anterior wall, however, is the backward projection of the tubercle of the epiglottis. It contains the ventricular folds, and between these and the vocal folds are the **ventricles of the larynx**. The portion caudal to the vocal folds is at first elliptical, but widens out, assumes a circular form, and is continuous with the tube of the trachea (Figs. 15-16; 15-17).

**ENTRANCE OF THE LARYNX.** The **entrance of the larynx** (Fig. 15-18) is bounded ventrally by the epiglottis; dorsally, by the apices of the arytenoid cartilages, the corniculate cartilages, and the interarytenoid notch; and on either side, by a fold of mucous membrane, enclosing ligamentous and muscular fibers, which is stretched between the side of the epiglottis and the apex of the arytenoid cartilage. This is the **aryepiglottic fold**, on the posterior part of the margin of which the cuneiform cartilage forms a more or less distinct whitish prominence, the **cuneiform tubercle**.

**VESTIBULAR FOLDS.** The vestibular folds (*plicae ventriculares*; superior or false vocal cords) are two thick folds of mucous membrane, each of which encloses a narrow band of fibrous tissue, the **vestibular ligament**, which is attached ventrally to the angle of the thyroid cartilage, immediately below the attachment of the epiglottis, and dorsally to the ventrolateral surface of the arytenoid cartilage, a short distance above the vocal process. The caudal border of this ligament, enclosed in mucous membrane, forms a free crescentic margin, which constitutes the upper boundary of the ventricle of the larynx.

**VOCAL FOLDS.** The vocal folds (*plicae vocales*; inferior or true vocal cords) enclose two strong bands named the **vocal ligaments** or vocal cords (*inferior thyroarytenoid*). Each ligament consists of a band of yellow elastic tissue attached ventrally to the angle of the thyroid cartilage and dorsally to the vocal process of the arytenoid. Its caudal border is continuous with the thin lateral part of the conus elasticus. Its cranial border forms the boundary of the ventricle of the larynx. Laterally, the vocalis muscle lies paral-

**FIG. 15-16.** A dissection to show the right half of the conus elasticus. The right lamina of the thyroid cartilage and the subjacent muscles have been removed.

**FIG. 15-17.** Sagittal section of larynx, right half.

FIG. 15-18. The entrance to the larynx, posterior view.

lel with it. The ligament is covered medially by mucous membrane that is extremely thin and closely adheres to its surface.

**VENTRICLE.** The ventricle of the larynx (*ventriculus laryngis* [Morgagnii<sup>1</sup>; laryngeal sinus]) is a fusiform fossa, bounded by the free crescentic edge of the ventricular fold, by the straight margin of the vocal fold and by the mucous membrane covering the corresponding thyroarytenoid muscle. The anterior part of the ventricle leads by a narrow opening into a cecal pouch of mucous membrane of variable size called the **appendix**.

**APPENDIX.** The appendix of the laryngeal ventricle (*appendix ventriculi laryngis*; *laryngeal saccule*) is a membranous sac placed between the ventricular fold and the inner surface of the thyroid cartilage, occasionally extending as far as its cranial border or even higher. On the surface of its mucous membrane are the openings of 60 or 70 mucous glands, which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule that is continuous caudally with the ventricular ligament. Its medial sur-

face is covered by a few delicate muscular fasciculi that arise from the apex of the arytenoid cartilage and become lost in the aryepiglottic fold of mucous membrane; laterally it is separated from the thyroid cartilage by the thyroepiglotticus. These muscles compress the sac and express the secretion it contains upon the vocal folds to lubricate their surfaces.

**RIMA GLOTTIDIS.** The rima glottidis (Fig. 15-19) is the elongated fissure or opening

FIG. 15-19. Laryngoscopic view of interior of larynx.

<sup>1</sup>Giovanni Battista Morgagni (1682-1771): An Italian anatomist and pathologist (Padua).

between the vocal folds ventrally and the bases and vocal processes of the arytenoid cartilages dorsally. It is therefore subdivided into a larger anterior intramembranous part (*glottis vocalis*), which measures about three-fifths of the length of the entire aperture, and a posterior intercartilaginous part (*glottis respiratoria*). Posteriorly it is limited by the mucous membrane passing between the arytenoid cartilages. The rima glottidis is the narrowest part of the cavity of the larynx, and its level corresponds with the bases of the arytenoid cartilages. Its length, in the male, is about 23 mm; in the female, from 17 to 18 mm. The width and shape of the rima glottidis vary with the movements of the vocal cords and arytenoid cartilages during respiration and phonation. In the condition of rest, i.e., when these structures are uninfluenced by muscular action, as in quiet respiration, the intermembranous part is triangular, with its apex in front and its base behind (the latter is represented by a line, about 8 mm long, connecting the anterior ends of the vocal processes, while the medial surfaces of the arytenoids are parallel to each other, and hence the intercartilaginous part is rectangular). During extreme adduction of the vocal folds, as in the emission of a high note, the intermembranous part is reduced to a linear slit by the apposition of the vocal folds, while the intercartilaginous part is triangular, its apex corresponding to the anterior ends of the vocal processes of the arytenoids, which are approximated by the medial rotation of the cartilages. Conversely, in extreme abduction of the vocal folds, as in forced inspiration, the arytenoids and their vocal processes are rotated lateralward and the intercartilaginous part is triangular, but with its apex directed backward. In this condition the entire glottis is somewhat lozenge-shaped, the widest part of the aperture corresponding with the attachments of the vocal folds to the vocal processes.

### Muscles

The muscles of the larynx are extrinsic, passing between the larynx and parts around (described in Chapter 6), and intrinsic, confined entirely to the larynx.

The intrinsic muscles are:

Cricothyroid  
Posterior cricoarytenoid

Lateral cricoarytenoid  
Arytenoid  
Thyroarytenoid

**CRICOTHYROID.** The triangular cricothyroid muscle (Fig. 15-20) arises from the front and lateral part of the cricoid cartilage; its fibers are arranged in two groups. The caudal fibers constitute a *pars obliqua* and slant backward to the anterior border of the inferior cornu; the anterior fibers, forming a *pars recta*, run cranialward, backward, and lateralward to the posterior part of the lower border of the lamina of the thyroid cartilage. The medial borders of the muscles on the two sides are separated by a triangular interval, occupied by the middle cricothyroid ligament.

**POSTERIOR CRICOARYTENOID.** The posterior cricoarytenoid (Fig. 15-20) arises from the broad depression on the corresponding half of the posterior surface of the lamina of the cricoid cartilage; its fibers run cranialward and lateralward, and converge to be inserted into the back of the muscular process of the arytenoid cartilage. The uppermost fibers are nearly horizontal, the middle are oblique, and the lowest are almost vertical.

**LATERAL CRICOARYTENOID.** The lateral cricoarytenoid (Fig. 15-22) is oblong and

Fig. 15-20. Side view of the larynx, showing muscular attachments.

smaller than the posterior cricoarytenoid muscle. It arises from the cranial border of the arch of the cricoid cartilage, and passing obliquely upward and backward, is inserted into the front of the muscular process of the arytenoid cartilage.

**ARYTENOID.** The arytenoid (Fig. 15-21) is a single muscle that fills up the posterior concave surfaces of the arytenoid cartilages. It arises from the posterior surface and lateral border of one arytenoid cartilage, and is inserted into the corresponding parts of the opposite cartilage. It consists of oblique and transverse parts. The **oblique arytenoid**, the more superficial, forms two fasciculi that pass from the base of one cartilage to the apex of the opposite one, and therefore cross each other like the limbs of the letter X. A few fibers are continued around the lateral margin of the cartilage, and are prolonged into the aryepiglottic fold; they are sometimes described as a separate muscle, the **aryepiglotticus**. The **transverse arytenoid** crosses transversely between the two cartilages.

**THYROARYTENOID.** The thyroarytenoid (Figs. 15-22; 15-23) is a broad, thin, muscle that lies parallel with and lateral to the vocal fold and supports the wall of the ventricle and its appendix. It arises from the caudal

FIG. 15-21. Muscles of larynx, posterior view.

FIG. 15-22. Muscles of larynx, side view. Right lamina of thyroid cartilage removed.

half of the angle of the thyroid cartilage and from the middle cricothyroid ligament. Its fibers pass dorsalward and lateralward, to be inserted into the base and anterior surface of the arytenoid cartilage. The more medial fibers of the muscle can be differenti-

FIG. 15-23. Muscles of the larynx, seen from above. (Enlarged.)

ated as a band that is inserted into the vocal process of the arytenoid cartilage and into the adjacent portion of its anterior surface; it is termed the **vocalis**, and lies parallel with the vocal ligament, to which it adheres.

Many fibers of the thyroarytenoid are prolonged into the aryepiglottic fold, where some of them become lost, while others are continued to the margin of the epiglottis. They have received a distinctive name, **thyroepiglotticus**, and are sometimes described as a separate muscle. A few fibers extend along the wall of the ventricle from the lateral wall of the arytenoid cartilage to the side of the epiglottis and constitute the **ventricularis** muscle.

**ACTIONS.** The actions of the muscles of the larynx may be conveniently divided into two groups: (1) those that open and close the glottis; (2) those that regulate the degree of tension of the vocal folds.

The *posterior cricoarytenoids* separate the vocal folds and, consequently, **open** the glottis by rotating the arytenoid cartilages outward around a vertical axis passing through the cricoarytenoid joints, so that their vocal processes and the vocal folds attached to them become widely separated.

The *lateral cricoarytenoids* **close** the glottis by rotating the arytenoid cartilages inward, so as to approximate their vocal processes.

The *arytenoid* approximates the arytenoid cartilages, and thus **closes** the opening of the glottis, especially at its back part.

The *cricothyroids* produce **tension** and elongation of the vocal folds by drawing up the arch of the cricoid cartilage and tilting back the upper border of its lamina; the distance between the vocal processes and the angle of the thyroid is thus increased and the folds are elongated.

The *thyroarytenoids*, consisting of two parts having different attachments and different directions, have a rather complicated action. Their main action is to draw the arytenoid cartilages forward toward the thyroid and thus shorten and relax the vocal folds. Their lateral portions rotate the arytenoid cartilage inward and thus narrow the rima glottidis by bringing the two vocal folds together. Certain minute fibers of the vocalis division, inserting obliquely upon the vocal ligament and designated as the **aryvocalis muscle**, are considered by Strong (1935) to be chiefly responsible for the control of pitch, through their ability to regulate the length of the vibrating part of the vocal folds.

The manner in which the entrance of the larynx is closed during deglutition is discussed in Chapter 16.

### Structure

**MUCOUS MEMBRANE.** The mucous membrane of the larynx is continuous with that lining the mouth, pharynx, trachea and

bronchi, and is prolonged into the lungs. It lines the posterior surface and the upper part of the anterior surface of the epiglottis, to which it is closely adherent, and helps to form the aryepiglottic folds, which bound the entrance of the larynx. It lines the whole of the cavity of the larynx; by its reduplication, it forms the chief part of the vestibular fold, and from the ventricle, it is continued into the ventricular appendix. It is then reflected over the vocal ligament, where it is thin and intimately adherent, covers the inner surface of the conus elasticus and cricoid cartilage, and is ultimately continuous with the lining membrane of the trachea. The anterior surface and the upper half of the posterior surface of the epiglottis, the upper part of the aryepiglottic folds, and the vocal folds are covered by stratified squamous epithelium; all the rest of the laryngeal mucous membrane is covered by columnar ciliated cells, but patches of stratified squamous epithelium are found in the mucous membrane above the glottis.

**GLANDS.** The mucous membrane of the larynx is furnished with numerous mucus-secreting glands, the orifices of which are found in nearly every part; they are plentiful upon the epiglottis, being lodged in little pits in its substance; they are also found in large numbers along the margin of the aryepiglottic fold in front of the arytenoid cartilages, where they are termed the **arytenoid glands**. They exist also in large numbers in the ventricular appendages. None are found on the free edges of the vocal folds.

**VESSELS.** The chief **arteries** of the larynx are the laryngeal branches derived from the superior and inferior thyroid arteries. The **veins** accompany the arteries; those accompanying the superior laryngeal artery join the superior thyroid vein, which opens into the internal jugular vein, while those accompanying the inferior laryngeal artery join the inferior thyroid vein, which opens into the brachiocephalic vein. The **lymphatic vessels** consist of two sets, superior and inferior. The former accompany the superior laryngeal artery and pierce the thyrohyoid membrane, to end in the nodes situated near the bifurcation of the common carotid artery. Of the latter, some pass through the middle cricothyroid ligament and open into nodes lying in front of that ligament or in front of the upper part of the trachea, while others pass to the deep cervical nodes and to the nodes accompanying the inferior thyroid artery.

**NERVES.** The **nerves** are derived from the vagus nerve by way of the internal and external branches of the superior laryngeal nerve and from the recurrent nerve. The internal laryngeal branch is sensory.

It enters the larynx by piercing the posterior part of the thyrohyoid membrane above the superior laryngeal vessels, and divides into three branches: one is distributed to both surfaces of the epiglottis; a second, to the aryepiglottic fold; and a third, the largest, supplies the mucous membrane over the back of the larynx and communicates with the recurrent nerve. The external laryngeal branch supplies the cricothyroid muscle. The recurrent nerve passes cranialward beneath the caudal border of the constrictor pharyngis inferior immediately dorsal to the cricothyroid joint. It supplies all the muscles of the larynx except the cricothyroid. The sensory branches of the laryngeal nerves form subepithelial plexuses, from which fibers end between the cells covering the mucous membrane.

Over the posterior surface of the epiglottis, in the aryepiglottic folds, and less regularly in some other

parts, taste buds similar to those in the tongue are found.

Fibers from the sympathetic nerves supply the blood vessels and glands.

## TRACHEA AND BRONCHI

### *Trachea*

The **trachea** or **windpipe** (Fig 15-24) is a cartilaginous and membranous tube, that extends from the larynx, on a level with the sixth cervical vertebra, to the cranial border of the fifth thoracic vertebra, where it divides into the two bronchi. The trachea is nearly but not quite cylindrical, being flat-

**FIG. 15-24.** Front view of cartilages of larynx, trachea, and bronchi.

tened dorsally; its length measures about 11 cm; its diameter, from side to side, is from 2 to 2.5 cm, being always greater in the male than in the female. In the child the trachea is smaller, more deeply placed, and more movable than in the adult.

**RELATIONS.** The *ventral surface* of the trachea is covered, **in the neck**, by the isthmus of the thyroid gland, the inferior thyroid veins, the thyroid ima artery (when that vessel exists), the sternothyroid and sternohyoid muscles, the cervical fascia, and, more superficially, by the anastomosing branches between the anterior jugular veins. **In the thorax**, it is covered by the manubrium sterni, the remains of the thymus, the left brachiocephalic vein, the aortic arch, the brachiocephalic and left common carotid arteries, and the deep cardiac plexus. *Dorsally* it is in contact with the esophagus. *Laterally, in the neck*, it is in relation with the common carotid arteries, the right and left lobes of the thyroid gland, the inferior thyroid arteries, and the recurrent nerves; **in the thorax**, it lies in the superior mediastinum, and is in relation on the right side with the pleura and right vagus, and near the root of the neck with the brachiocephalic artery; on its left side are the left recurrent nerve, the aortic arch, and the left common carotid and subclavian arteries.

**CLINICAL CONSIDERATIONS.** The operation for **tracheotomy**, when performed as an emergency, is best carried out by piercing the neck 1 cm below the cricoid cartilage and opening the trachea between the second and third cartilaginous rings. The thyroid and cricoid cartilages are avoided because of subsequent scarring of the larynx. The isthmus of the thyroid gland is usually caudal to the first two tracheal cartilages and no blood vessels of appreciable size are present. Caudal to the thyroid gland, the trachea is situated much deeper than above it because of Burns's space,<sup>1</sup> and large veins are likely to be present.

### Right Bronchus

The right bronchus is wider, shorter, and less abrupt in its divergence from the trachea than the left. It is about 2.5 cm long and enters the right lung nearly opposite the fifth thoracic vertebra. The azygos vein arches over it and the pulmonary artery lies at first inferior and then ventral to it. It gives rise to three subsidiary bronchi, one to each of the lobes. The superior lobe bronchus comes off above the pulmonary artery and has been called, therefore, the **eparterial bronchus**. The bronchi to the middle and inferior lobes

separate below the pulmonary artery and are accordingly **hyparterial** in position.

The **right superior lobe bronchus** divides into three branches named, according to the bronchopulmonary segments that they enter, the bronchus for the apical segment, for the posterior segment, and for the anterior segment. The **right middle lobe bronchus** divides into two branches, the bronchus for the lateral and for the medial segments. The **right inferior lobe bronchus** first gives off the bronchus to the superior segment, and then divides into four bronchi for the basal segments: the medial basal, anterior basal, lateral basal, and posterior basal segments.

### Left Bronchus

The left bronchus is smaller in caliber but about twice as long as the right (5 cm). It passes under the aortic arch and crosses ventral to the esophagus, thoracic duct, and descending aorta. It is superior to the pulmonary artery at first, then dorsal, and finally passes inferior to the artery before it divides into the bronchi for the superior and inferior lobes. Both lobar bronchi, therefore, are hyparterial in position.

The **left superior lobe bronchus** divides into two branches, one of which is distributed to a portion of the left lung corresponding to the right superior lobe; the other, to a portion corresponding to the right middle lobe. These two branches are called the superior division and inferior division bronchi to differentiate them from segmental bronchi. The **superior division bronchus** of the left superior lobe divides into branches for the apical posterior segment and the anterior segment. The **inferior division bronchus** divides into bronchi for the superior and inferior segments. The **left inferior lobe bronchus** gives off first the bronchus for the superior segment and then divides into three branches for basal segments: the anterior medial basal, lateral basal, and posterior basal segments.

The picture seen through a bronchoscope may be reproduced if a section is made across the trachea and a bird's-eye view taken of its interior (Fig. 15-25). At the bottom of the trachea, the septum that separates the two bronchi is visible as a spur (in bronchoscopic terminology) and is named the **carina**. The **carina** is placed to the left of the

<sup>1</sup>Allen Burns (1781-1813): A Scottish anatomist (Glasgow).

**FIG. 15-25.** Bifurcation of the trachea, viewed from above, with the interior showing the carina as it would be seen through a bronchoscope.

middle line and the right bronchus appears as a more direct continuation of the trachea than the left. Because of this asymmetry and because the right bronchus is larger in diameter than the left, foreign bodies that enter the trachea have a tendency to drop into the right bronchus rather than into the left.

### Structure

The trachea and extrapulmonary bronchi are composed of imperfect rings of hyaline cartilage, fibrous tissue, muscular fibers, mucous membrane, and glands (Fig. 15-26).

**CARTILAGES.** The cartilages of the trachea number from 16 to 20; each forms an imperfect ring, which occupies the anterior two-thirds or so of the circumference of the tra-

chea, being deficient behind, where the tube is completed by fibrous tissue and non-striated muscular fibers. The cartilages are placed horizontally above each other, separated by narrow intervals. They measure about 4 mm deep and 1 mm thick. Their outer surfaces are flattened in a vertical direction, but internally, they are convex, the cartilages being thicker in the middle than at the margins. Two or more of the cartilages often unite, partially or completely, and they are sometimes bifurcated at their extremities. They are highly elastic, but may become calcified in advanced life. In the right bronchus the cartilages vary in number from six to eight; in the left, from nine to twelve. They are shorter and narrower than those of the trachea, but have the same shape and arrangement. The special tracheal cartilages are the first and the last (Fig. 15-24).

The **first cartilage** is broader than the rest and often divided at one end; it is connected by the cricotracheal ligament with the caudal border of the cricoid cartilage, with which or with the succeeding cartilage it is sometimes blended.

The **last cartilage** is thick and broad in the middle, because its lower border is prolonged into a triangular hook-shaped process that curves downward and backward between the origins of the two bronchi. It

**FIG. 15-26.** Cross section of trachea, adult cadaver. 5 X.

ends on each side in an imperfect ring, which encloses the commencement of each bronchus. The cartilage above the last is somewhat broader than the others at its center.

**FIBROUS MEMBRANE.** The cartilages are enclosed in an elastic fibrous membrane that consists of two layers; one, the thicker, passes over the outer surface of the ring, and the other passes over the inner surface. At the cranial and caudal margins of the cartilages the two layers blend together to form a single membrane that connects the rings with one another. In the space between the ends of the rings dorsally, the membrane forms a single layer also.

**MUSCULAR TISSUE.** The muscular tissue consists of two layers of nonstriated muscle, longitudinal and transverse, between the ends of the cartilages. The **longitudinal fibers** are external and consist of a few scattered bundles. The **transverse fibers** (trachealis muscle) are arranged internally in branching and anastomosing bands that extend more or less transversely (Fig. 15-26).

**MUCOUS MEMBRANE.** The mucous membrane is continuous above with that of the larynx and below with that of the bronchi. It consists of areolar and lymphoid tissue and has a well-marked basement membrane that supports a stratified epithelium, the surface layer of which is columnar and ciliated, while the deeper layers are composed of oval or rounded cells. Beneath the basement membrane is a distinct layer of longitudinal elastic fibers with a small amount of intervening areolar tissue. The submucous layer is composed of a loose meshwork of connective tissue that contains large blood vessels, nerves, and mucous glands; the ducts of the latter pierce the overlying layers and open on the surface (Fig. 15-27).

**VESSELS AND NERVES.** The trachea is supplied with blood by the inferior thyroid **arteries**. The **veins** end in the thyroid venous plexus. The **nerves** are derived from the vagus and the recurrent nerves and from the sympathetic trunk; they are distributed to the trachealis muscles and between the epithelial cells.

## PLEURA

Each lung is invested by an exceedingly delicate serous membrane, the **pleura**, which is arranged in the form of a closed invagi-

**Fig. 15-27.** Section through wall of human trachea. c, Cartilage; e.p., pseudostratified ciliated epithelium; g.c., goblet cell; m.g., mucous gland. 8  $\times$ . (Sobotta.)

nated sac. A portion of the serous membrane covers the surface of the lung and dips into the fissures between its lobes; it is called the **pulmonary pleura**. The rest of the membrane lines the inner surface of the chest wall, covers the diaphragm, and is reflected over the structures occupying the middle of the thorax; this portion is termed the **parietal pleura**. The two layers are continuous with each other around and below the root of the lung; in health they are in actual contact with each other, but the potential space between them is known as the **pleural cavity**. When the lung collapses or when air or fluid collects between the two layers, the cavity becomes apparent. The right and left pleural sacs are entirely separate from each other; between them are all the thoracic viscera except the lungs, and they touch each other only for a short distance ventrally, behind the upper part of the body of the sternum; the interval in the middle of the thorax between the two sacs is termed the **mediastinum**.

Different portions of the parietal pleura have received special names that indicate their position: thus, that portion which lines the inner surfaces of the ribs and intercostal muscles is the **costal pleura**; that clothing the convex surface of the diaphragm is the **dia-**

phragmatic pleura; that which rises into the neck, over the summit of the lung, is the **cupula of the pleura** (*cervical pleura*); and that which is applied to the other thoracic viscera is the **mediastinal pleura**.

### *Parietal Pleura*

Commencing at the sternum, the pleura passes lateralward, lining the costal cartilages, ribs, and intercostal muscles (Figs. 15-28; 15-29). At the dorsal part of the thorax, it passes over the sympathetic trunk and its branches and is reflected upon the sides of the bodies of the vertebrae, where it is separated by a narrow interval, the posterior mediastinum, from the opposite pleura. From the vertebral column the pleura passes to the side of the pericardium, which it covers to a slight extent before it covers the dorsal part of the root of the lung, from the caudal border of which a triangular sheet descends vertically toward the diaphragm. This sheet is the posterior layer of a fold known as the **pulmonary ligament**.

From the dorsal portion of the lung root, the pleura may be traced over the costal surface of the lung, over its apex and base, and also over the sides of the fissures between the lobes, onto its mediastinal surface and the ventral part of its root. It is continued from the caudal margin of the root as the anterior layer of the pulmonary ligament, and from this it is reflected onto the pericardium (**pericardial pleura**), and then to the dorsal surface of the sternum. Cranial to the level of the root of the lung, however, the mediastinal pleura passes uninterruptedly from the vertebral column to the sternum over the structures in the superior mediastinum. It covers the cranial surface of the diaphragm and extends, ventrally, as low as the costal cartilage of the seventh rib; at the side of the chest, it extends to the caudal border of the tenth rib on the left side and to the cranial border of the same rib on the right side. Dorsally, it reaches as low as the twelfth rib, and sometimes even to the transverse process of the first lumbar vertebra.

The **cupula** projects through the superior

**FIG. 15-28.** Front view of thorax, showing the relations of the pleurae and lungs to the chest wall. Phrenicocostal and costomediastinal sinus in blue; lungs in purple.

**FIG. 15-29.** Lateral view of thorax, showing the relations of the pleurae and lungs to the chest wall. Phrenicocostal and costomediastinal sinus in blue; lungs in purple.

opening of the thorax into the neck, extending from 2.5 to 5 cm above the sternal end of the first rib; this portion of the sac is strengthened by a dome-like expansion of fascia (**Sibson's<sup>1</sup> fascia**), which is attached ventrally to the inner border of the first rib and dorsally to the anterior border of the transverse process of the seventh cervical vertebra. This is covered and strengthened by a few spreading muscular fibers derived from the scalene muscles called the *scalenus minimus*.

In the ventral part of the chest, the two pleural sacs behind the manubrium are separated by an angular interval; the reflection is represented by a line drawn from the sternoclavicular articulation to the midpoint of the junction of the manubrium with the body of the sternum. From this point the two pleurae descend in close contact to the level of the fourth costal cartilages. The line of reflection on the right side is continued cau-

dalward in nearly a straight line to the xiphoid process, and then turns lateralward, while on the left side the line of reflection diverges lateralward and is continued caudalward, close to the left border of the sternum, as far as the sixth costal cartilage. The caudal limit of the pleura is on a considerably lower level than the corresponding limit of the lung, but does not extend to the attachment of the diaphragm, so that caudal to the line of reflection from the chest wall on to the diaphragm, the pleura is in direct contact with the rib cartilages and the *intercostales interni*. Moreover, in ordinary inspiration the thin inferior margin of the lung does not extend as far as the line of the pleural reflection, so that the costal and diaphragmatic pleurae are in contact here, the intervening narrow slit being termed the **costodiaphragmatic recess** (*phrenicocostal sinus*). A similar condition exists behind the sternum and rib cartilages, where the anterior thin margin of the lung falls short of the line of pleural reflection, and where the slit-like cavity between the two layers of pleura forms the **costomediastinal recess** (*costomediastinal sinus*).

The line along which the right pleura is reflected from the chest wall to the diaphragm starts ventrally, immediately below the seventh sternocostal joint, and runs caudalward and dorsalward behind the seventh costal cartilage, thus crossing the tenth rib in the midaxillary line, from which it is prolonged to the level of the spinous process of the twelfth thoracic vertebra. The reflection of the left pleura follows at first the ascending part of the sixth costal cartilage, and in the rest of its course is slightly lower than that of the right side.

The free surface of the pleura is smooth, glistening, and moistened by a serous fluid; its attached surface adheres intimately to the lung and to the pulmonary vessels as they emerge from the pericardium; it also adheres to the cranial surface of the diaphragm. Throughout the rest of its extent it is easily separable from the adjacent parts.

The right pleural sac is shorter, wider, and reaches higher in the neck than the left.

### **Pulmonary Ligament**

The root of the lung is covered by pleura, except at its caudal border where the investing layers come into contact. Here they form

<sup>1</sup>Francis Sibson (1814-1876): An English physician (London).

a sort of mesenteric fold, the **pulmonary ligament**, which extends between the mediastinal surface of the lung and the pericardium. Just above the diaphragm the ligament ends in a free falciform border. It retains the lower part of the lung in position.

### Structure

Like other serous membranes, the pleura is composed of a single layer of flattened mesothelial cells resting upon a delicate connective tissue membrane, beneath which lies a stroma of collagenous tissue containing several prominent networks of yellow elastic fibers. Blood vessels, lymphatics, and nerves are distributed in the substance of the pleura.

**VESSELS AND NERVES.** The **arteries** of the pleura are derived from the intercostal, internal thoracic, musculophrenic, thymic, pericardiac, pulmonary, and bronchial vessels. The **veins** correspond to the arteries. The **lymphatics** are described in Chapter 10.

The **nerves** of the parietal pleura are derived from the phrenic, intercostal, vagus, and sympathetic nerves; those of the pulmonary pleura, from the vagus and sympathetic nerves through the pulmo-

nary plexuses at the hilum of the lung. It is believed that nerves accompany the ramifications of the bronchial arteries in the pulmonary pleura.

### MEDIASTINUM

The **mediastinum** is interposed as a partition in the median portion of the thorax, separating the parietal pleural sacs of the two lungs (Fig. 15-31). It extends from the sternum ventrally to the vertebral column dorsally and comprises all the thoracic viscera, except the lungs and pleurae, embedded in a thickening and expansion of the subserous fascia of the thorax. It is divided arbitrarily, for the purposes of description, into cranial and caudal parts by a plane that extends from the sternal angle to the caudal border of the fourth thoracic vertebra. The cranial part is named the **superior mediastinum**; the caudal part is again subdivided into three parts: the **anterior mediastinum**, ventral to the pericardium; the **middle mediastinum**, containing the pericardium; and the **posterior mediastinum**, dorsal to the pericardium.

The **superior mediastinum** (Fig. 15-30) is bounded by the superior aperture of the thorax; by the plane of the superior limit of the pericardium; by the manubrium; by the

**FIG. 15-30.** Transverse section through the upper margin of the second thoracic vertebra, showing the superior mediastinum. (Braune.)

**Fig. 15-31.** A transverse section of the thorax showing the contents of the middle and the posterior mediastinum. The pleural and pericardial cavities are exaggerated since normally there is no space between parietal and visceral pleurae and between pericardium and heart.

upper four thoracic vertebrae; and laterally, by the mediastinal pleurae of the two lungs. It contains the origins of the sternohyoid and sternothyroid muscles and the lower ends of the longus colli muscles; the aortic arch; the brachiocephalic artery and the thoracic portions of the left common carotid and the left subclavian arteries; the brachiocephalic veins and the upper half of the superior vena cava; the left highest intercostal vein; the vagus, cardiac, phrenic, and left recurrent nerves; the trachea, esophagus, and thoracic duct; and the remains of the thymus, and some lymph nodes.

The **anterior mediastinum** (Fig. 15-31) is bounded ventrally by the body of the sternum and because of the position of the heart, the left transversus thoracis muscle and parts of the fourth, fifth, sixth, and seventh costal cartilages. It is bounded dorsally by the parietal pericardium and extends caudalward as far as the diaphragm. Besides a few lymph nodes and vessels, it contains only a thin layer of subserous fascia which is separated from the endotheracic or deep fascia superiorly by a fascial cleft, but there is a firm attachment in its caudal part that forms the pericardiosternal ligament.

The **middle mediastinum** (Fig. 15-31) is the broadest part of the interpleural septum. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava with the azygos vein opening into it, the pulmonary trunk dividing into its two branches, the right and left pulmonary veins, and the phrenic nerves.

The **posterior mediastinum** (Fig. 15-31) is an irregularly shaped mass running parallel with the vertebral column and, because of the slope of the diaphragm, it extends caudally beyond the pericardium. It is bounded ventrally, by the pericardium and, more caudally, by the diaphragm; dorsally, by the vertebral column from the lower border of the fourth to the twelfth thoracic vertebra; and on either side, by the mediastinal pleurae. It contains the thoracic part of the descending aorta, the azygos and hemiazygos veins, the vagus and splanchnic nerves, the bifurcation of the trachea and the two bronchi, the esophagus, the thoracic duct, and many large lymph nodes.

Some authorities include the bifurcation of the trachea, the two bronchi, and the roots of the two lungs in the middle mediastinum.

## Lungs (Pulmones)

The **lungs** are the essential organs of respiration; they are placed on either side within the thorax and are separated from each other by the heart and other contents of the mediastinum (Fig. 12-76). The substance of the lung has a light, porous, spongy texture; it floats in water and crepitates when handled owing to the presence of air in the alveoli. It is also highly elastic, hence the retracted state of these organs when they are removed from the closed cavity of the thorax. The surface is smooth, shiny, and marked out into numerous polyhedral areas that indicate the lobules of the organ: each of these areas is crossed by numerous lighter lines.

At birth the lungs are pinkish-white in color; in adult life the color is a slaty gray, mottled in patches, and as age advances, this mottling assumes a black color. The coloring matter consists of granules of carbon deposited in the areolar tissue near the surface of the organ. It increases in quantity as age advances, and is more abundant in males than in females. As a rule, the posterior border of the lung is darker than the anterior.

The right lung usually weighs about 625 gm, the left weighs 567 gm, but much variation is met according to the amount of blood or serous fluid they may contain. The lungs are heavier in males than in females, their proportion to the body being 1 to 37 in the former and 1 to 43 in the latter. The vital capacity, the quantity of air that can be exhaled by the deepest expiration after making the deepest inspiration, varies greatly with the individual; an average for an adult man is 3700 ml. The total volume of the fully expanded lungs is about 6500 ml; this includes both tissues and contained air. The tidal air, the amount of air breathed in or out during quiet respiration, is about 500 ml for the adult man. Various calculations indicate that the total epithelial area of the respiratory and nonrespiratory surfaces during ordinary deep inspiration of the adult is not greater than 70 square meters.

Each lung is conical and presents for examination an **apex**, a **base**, three **borders**, and two **surfaces**.

The **apex** is rounded and extends into the root of the neck, reaching 2.5 to 5 cm above the level of the sternal end of the first rib. A sulcus is produced by the subclavian artery as it curves ventral to the pleura and runs

cranialward and lateralward immediately below the apex.

The **base** is broad, concave, and rests upon the convex surface of the diaphragm, which separates the right lung from the right lobe of the liver, and the left lung from the left lobe of the liver, the stomach, and the spleen. Since the diaphragm extends higher on the right than on the left side, the concavity on the base of the right lung is deeper than that on the left. Laterally and dorsally, the base is bounded by a thin, sharp margin that projects for some distance into the phrenicocostal sinus of the pleura, between the lower ribs and the costal attachment of the diaphragm. The base of the lung descends during inspiration and ascends during expiration.

### SURFACES

The **costal surface** (external or *thoracic surface*) is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, being deeper dorsally than ventrally. It is in contact with the costal pleura and presents, in specimens that have been hardened in situ, slight grooves corresponding with the overlying ribs.

The **mediastinal surface** (inner surface) is divided into a mediastinal and a vertebral portion. The **mediastinal portion** is in contact with the mediastinal pleura. It has a deep concavity, the **cardiac impression**, which accommodates the pericardium. Dorsal and cranial to this concavity is a slight depression named the **hilum**, through which the structures that form the root of the lung enter and leave.

On the **right lung** (Fig. 15-33), immediately cranial to the hilum, is an arched furrow that accommodates the azygos vein. Running cranialward and then arching lateralward some little distance below the apex is a wide groove for the superior vena cava and right brachiocephalic vein. Dorsal to the hilum and the attachment of the pulmonary ligament is a vertical groove for the esophagus; this groove becomes less distinct caudally, owing to the inclination of the lower part of the esophagus to the left of the midline. Ventral and to the right of the lower part of the esophageal groove is a deep concavity for the extrapericardiac portion of the thoracic part of the inferior vena cava.

On the **left lung** (Fig. 15-34), immediately

FIG. 15-32. Front view of heart and lungs.

cranial to the hilum, is a well-marked curved furrow produced by the aortic arch, and running cranialward from this toward the apex is a groove that accommodates the left subclavian artery; a slight impression ventral to the latter and close to the margin of the lung lodges the left innominate vein. Dorsal to the hilum and pulmonary ligament is a vertical furrow produced by the descending aorta, and ventral to this, near the base of the lung, the lower part of the esophagus causes a shallow impression.

### BORDERS

The **inferior border** is thin and sharp where it separates the base from the costal surface and extends into the phrenicocostal sinus; medially, where it divides the base from the mediastinal surface, it is blunt and rounded.

The **anterior border** is thin and sharp and overlaps the ventral surface of the heart and pericardium. The anterior border of the right lung is almost vertical and projects into the costomediastinal sinus; that of the left lung has an angular notch, the **cardiac notch**, in which the pericardium comes into contact with the sternum. Opposite this notch, the anterior margin of the left lung is situated a little distance lateral to the line of reflection of the corresponding part of the pleura.

### FISSURES AND LOBES

**RIGHT LUNG.** The right lung is divided into three lobes (superior, middle, and inferior) by two interlobar fissures.

The **oblique fissure** separates the inferior from the middle and superior lobes and corresponds with the oblique fissure in the left lung. Its direction is more vertical, however,

FIG. 15-33. Mediastinal surface of right lung.

and it cuts the lower border about 7.5 cm dorsal to its extremity.

The **horizontal fissure** separates the superior from the middle lobe. It begins in the previous fissure near the dorsal border of the lung, and running horizontally, cuts the ventral border on a level with the sternal end of the fourth costal cartilage; on the mediastinal surface it may be traced dorsal to the hilum. The middle lobe, the smallest lobe of the right lung, is wedge-shaped and includes the lower part of the ventral border and the ventral part of the base of the lung.

The right lung is shorter by 2.5 cm than the left because the diaphragm rises higher on the right side, and it is broader because of the inclination of the heart to the left side. Its total capacity is greater, however, and it weighs more than the left lung.

**LEFT LUNG.** The left lung is divided into two lobes, a superior and an inferior, by an **oblique fissure** that extends from the costal to the mediastinal surface of the lung both above and below the hilum. As seen on the surface, this fissure begins on the mediasti-

nal surface of the lung at the hilum, and runs dorsalward and cranialward to the posterior border, which it crosses at a point about 6 cm below the apex. It then extends caudalward and ventralward over the costal surface, to reach the lower border near its extremity, and its further course can be followed across the mediastinal surface as far as the hilum. The superior lobe includes the apex, the anterior border, a considerable part of the costal surface, and the greater part of the mediastinal surface of the lung. The inferior lobe is larger than the superior and comprises almost the whole of the base, a large portion of the costal surface, and the greater part of the vertebral part of the medial surface.

#### ROOT

The root of the lung (*radix pulmonis*) (Figs. 15-33; 15-34) is formed by the bronchus, pulmonary artery, pulmonary veins, bronchial arteries and veins, pulmonary

FIG. 15-34. Mediastinal surface of left lung.

plexuses of nerves, lymphatic vessels, and bronchial lymph nodes. These structures are all embedded in mediastinal connective tissue and the entire mass is encircled by a reflection of the pleura. It corresponds to the hilum, which is near the center of the mediastinal surface of the lung, dorsal to the cardiac impression and closer to the posterior than the anterior border. The root of the right lung lies dorsal to the superior vena cava and the right atrium, and the azygos vein arches over it (Fig. 12-76). The root of the left lung is ventral to the descending aorta and inferior to the aortic arch (Fig. 12-77). The phrenic nerve, the pericardiophrenic artery and vein, and the anterior pulmonary plexus of nerves are ventral, while the vagus nerve and its posterior pulmonary plexus are dorsal to the root of the lung on both sides. Caudal to the root of each lung, the reflection of the pleura from mediastinum to lung is prolonged downward toward the diaphragm as the pulmonary ligament (p. 1382).

The chief structures of the roots of both lungs have a similar relation to each other in a dorsoventral direction, but there is a difference in their superior and inferior relations on the two sides. Thus the pulmonary

veins are ventral, the bronchi dorsal, and the pulmonary arteries between, on both sides. On the right side, the superior lobe bronchus is superior and the pulmonary artery is slightly lower; next are the bronchi to the middle and inferior lobes, and most inferior is the pulmonary vein (Fig. 15-33). On the left side, the pulmonary artery is superior, the pulmonary veins inferior, and the bronchus between (Fig. 15-34).

#### FURTHER SUBDIVISION OF THE LUNG

The importance of certain smaller units of structure of the lungs, called bronchopulmonary segments, has been emphasized by the thoracic surgeon, bronchoscopist, and radiologist. To interpret these units correctly, one should give particular attention to the concept that the lung is fundamentally the aggregate of all the branchings of the bronchus. According to this concept, a bronchopulmonary segment is that portion of the lung to which any particular bronchus is distributed, and the term might conceivably be applied to the lobule supplied by its lobular bronchus. In actual practice, however, it is

customary to restrict the term bronchopulmonary segment to the portion of the lung supplied by the direct branches of the lobar bronchi (and of the division bronchi in the case of the left superior lobe). These segments are as definite as the lobes, and their relative extent and position can be demonstrated by introducing different colored gelatin into their bronchi. It is possible, in many cases, to follow the delicate connective tissue between the segments and dissect them apart. That the majority of extra fissures follow the planes of separation between the segments also demonstrates their fundamental nature.

**BRONCHOPULMONARY SEGMENTS** (Fig. 15-35). The bronchopulmonary segments are named according to their positions in the lobes, and the bronchus to each is named after its segment. The right superior lobe has three segments: apical, posterior, and anterior. The right middle lobe has a lateral and a medial segment. The right inferior lobe has a superior and four basal segments: the medial basal, anterior basal, lateral basal, and posterior basal. The left superior lobe is first separated into two divisions, the superior division corresponding to the right superior lobe, and an inferior division corresponding to the right middle lobe. The superior division of the left superior lobe has an apical posterior and an anterior segment. The inferior division of the left superior lobe has a superior and an inferior segment. The left inferior lobe has a superior and three basal segments: anteromedial basal, lateral basal, and posterior basal.

**VARIATIONS.** The branching of the lobar bronchi to form segmental bronchi is reasonably constant. The superior lobe bronchus is somewhat more constant than the inferior lobe bronchus. In approximately 95% of the specimens, it is possible to identify three segmental bronchi coming from the right superior lobe bronchus, although in some of these cases, two segmental bronchi may seem to arise from a short common stem. The size of the lung segment supplied by a particular bronchus may be larger or smaller than expected, even when the branching appears at first glance to follow the usual pattern, because it may have exchanged a smaller branch bronchus with an adjacent segmental bronchus. In the case of the lower lobe bronchus, the superior and the medial basal segmental bronchi are about as constant as the branches in the superior lobe, but there is more variation in the anterior basal, lateral basal, and posterior basal segments. In somewhat less than 50% of the specimens, branches come from the posterior aspect of the infe-

rior lobe bronchus between the superior segmental and the basal segmental bronchi, or from the stem below the anterior basal segmental bronchus.

The branchings of the bronchi are designated according to the parts of the lungs that they ventilate. The two main bronchi correspond to the right and left lungs. The right bronchus is subdivided into three lobar bronchi for the superior, middle, and inferior lobes; the left bronchus is subdivided into two, for the superior and inferior lobes. Each lobar bronchus is subdivided into branchings for the bronchopulmonary segments depicted in Figure 15-36.

For the purpose of relating the smaller branchings of the bronchi to the ramifications of the pulmonary arteries and veins, they have been named and numbered by Boyden (1955) (see Fig. 15-36). In the lists of segmental bronchi, arteries, and veins, corresponding structures of the right and left lungs are placed opposite each other.

## BLOOD VESSELS OF THE LUNGS

The vessels that serve the special function of the lungs, that is, of aerating the blood, are the pulmonary arteries and veins and their connecting capillaries (Figs. 15-36 to 15-41). The blood supply for the purpose of nutrition to the tissues of the lungs is provided by the bronchial arteries and veins; these are discussed on page 1398.

**PULMONARY VESSELS.** The right and left **pulmonary arteries**, formed by the bifurcation of the pulmonary trunk, convey the deoxygenated blood to the right and left lungs. They divide into branches that accompany the bronchi, coursing chiefly along their dorsal surface. The bronchopulmonary segments are supplied by main intrasegmental branches of the pulmonary arteries, which are single for the most part, but which may arise as common trunks for adjacent segments (Boyden, 1955). The artery for one segment is likely to supply small branches to the neighboring segments. Distal to the alveolar duct, branches are distributed to each atrium, from which arise smaller radicles terminating in a dense capillary network in the walls of the alveoli.

The **pulmonary veins** are described in Chapter 9. The segmental veins are listed here according to the same classification used for the segmental arteries.

**Fig. 15-35.** The bronchopulmonary segments. The segmental branches of the bronchi are shown in corresponding colors. (After J. F. Huber, 1947.)

the anatomic units of the lung. The primary lobule consists of an alveolar duct, the air spaces connected with it, and blood vessels, lymphatics, and nerves (Fig. 15-42).

**INTRAPULMONARY BRONCHI.** The intrapulmonary bronchi divide and subdivide throughout the entire organ, the smallest subdivisions constituting the lobular bronchioles. The larger divisions consist of: (1) an outer coat of fibrous tissue, in which irregular plates of hyaline cartilage are found at intervals, with the most developed appearing at the points of division; (2) internal to the fibrous coat, an interlacing network of circularly disposed smooth muscle fibers, the bronchial muscle; and (3) most internally, the mucous membrane, which is lined by columnar ciliated epithelium resting on a basement membrane. The corium of the mucous membrane contains numerous elastic fibers that run longitudinally and a certain amount of lymphoid tissue; it also contains the ducts of mucous glands, the acini of which lie in the fibrous coat.

In the **lobular bronchioles** (terminal bronchioles), the ciliated epithelial cells become cuboidal, and cartilage plates cease to exist

when the diameter of the bronchiole reaches about 1 mm. Branching and anastomosing bands of smooth muscle fibers, continuous with those of the intrapulmonary bronchi, invest the bronchiole and its subdivisions to the point of junction between alveolar duct and atrium (Fig. 15-43).

Each bronchiole, according to Miller (1947), divides into two or more **respiratory bronchioles**, with scattered alveoli, and each of these again divides into several **alveolar ducts**, with a greater number of alveoli connected with them (Fig. 15-44). Each alveolar duct is connected with a variable number of irregularly spherical spaces, which also possess alveoli, the **atria**. With each atrium, a

**FIG. 15-44.** General scheme of a primary lobule, showing the subdivisions of (B) a respiratory bronchiole into two alveolar ducts; and the atria (A), alveolar sacs (S.A.L.) of one of these ducts. ALV', alveoli scattered along the bronchioles; P, pleura, 1, pulmonary artery, dividing into smaller radicles for each atrium, one of which terminates in a capillary plexus on the wall of an alveolus; 2, its branches to the respiratory bronchiole and alveolar duct; 3, pulmonary vein with its tributaries from the pleura 6, capillary plexus of alveolus, and wall of the atrium 9 and alveolar duct 10; 4, lymphatics; dotted areas at 7, 8, 9 and 10, indicating areas of lymphoid tissue; 5, bronchial artery terminating in a plexus on the wall of the bronchiole; 5', bronchial artery terminating in pleura. (Miller, *The Lung*, courtesy of Charles C Thomas.)

variable number (2 to 5) of **alveolar sacs** are connected which bear **alveoli** or air spaces on all parts of their circumference.

**ALVEOLI.** The alveoli are lined by a continuous layer of pulmonary alveolar epithelium. The nuclei of the epithelial cells protrude into the air spaces, and the perinuclear cytoplasm attenuates abruptly into thin sheets of cytoplasm. The cytoplasmic sheets, averaging about  $0.2 \mu\text{m}$  in thickness, rest on a basement membrane and face on the alveolar air spaces. The alveolar walls contain blood capillaries and collagenous, reticular, and elastic connective tissue fibers. The bar-

rier between the capillary blood and alveolar air includes two thin layers of cytoplasm, alveolar epithelium and capillary endothelium with adherent basement membranes for each. Tissue space between these two membranes may be potential or real, but they are not adherent and variable amounts of interstitial elements may separate them.

The fetal lung resembles a gland in that the alveoli have a small lumen and are lined by cubical epithelium. After the first respiration the alveoli become distended, and the epithelium takes on the characteristics of the adult.

**VESSELS.** The bronchial arteries supply blood for the nutrition of the lung; the right lung usually receives a single artery and the left lung receives two. They are derived from the ventral side of the upper part of the thoracic aorta or from the upper aortic intercostal arteries. Some are distributed to the bronchial glands and to the walls of the bronchi and pulmonary vessels; those supplying the bronchi extend as far as the respiratory bronchioles, where they form capillary plexuses that unite with similar plexuses formed by the pulmonary artery, both of which give rise to small venous trunks forming one of the sources of the pulmonary vein. Others are distributed in the interlobular areolar tissue and end partly in the deep and partly in the superficial bronchial veins. Lastly, some ramify upon the surface of the lung, beneath the pleura, where they form a capillary network.

The bronchial vein is formed at the root of the lung. It receives superficial and deep veins from a limited area about the hilum; the larger part of the blood supplied by the bronchial arteries is returned by the pulmonary veins. The bronchial vein ends on the right side in the azygos vein, and on the left side in the highest intercostal vein or in the accessory hemiazygos vein.

The lymphatics are described on page 894.

**NERVES.** The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and vagus nerves. The filaments from these plexuses accompany the bronchial tubes, supplying efferent fibers to the bronchial muscle and afferent fibers to the bronchial mucous membrane and probably to the alveoli of the lung. Small ganglia are found upon these nerves.

## The Digestive System

The **digestive system**, which provides the apparatus for the digestion of food, consists of the digestive tube and certain accessory organs.

The **digestive tube** (*alimentary canal*) is a musculomembranous tube, about 9 meters long, that extends from the mouth to the anus; it is lined throughout its entire extent by mucous membrane. Different names have been applied to the various parts of its course: at its commencement is the **mouth**, where provision is made for the mechanical division of the food (*mastication*), and for its admixture with a fluid secreted by the salivary glands (*insalivation*). Beyond this are the **pharynx** and **esophagus**, which convey food into the **stomach**, where it is stored for a time and where the first stages of the digestive process take place. The stomach is followed by the **small intestine**, which is divided for purposes of description into three parts: the **duodenum**, the **jejunum**, and the **ileum**. In the small intestine the process of digestion is completed and the resulting products are absorbed into the blood and

lacteal vessels. Finally the small intestine ends in the **large intestine**, made up of **cecum**, **colon**, **rectum**, and **anal canal**, the last terminating on the surface of the body at the **anus**.

The accessory organs are the **teeth**, for purposes of mastication; the three pairs of **salivary glands**—the **parotid**, the **submandibular**, and the **sublingual**—the secretion from which mixes with the food in the mouth and converts it into a bolus and acts chemically on one of its constituents; the **liver** and **pancreas**, two large glands in the abdomen, the secretions of which, in addition to that of numerous minute glands in the walls of the alimentary canal, assist in the process of digestion.

### Development of the Digestive System

The primitive digestive tube consists of two parts: (1) the **foregut**, within the cephalic flexure and dorsal to the heart; and (2) the **hindgut**, within the caudal flexure (Fig. 16-1).

**FIG. 16-1.** Human embryo about 15 days old. Brain and heart represented from right side. Digestive tube and yolk sac in median section. (After His.)

Between these is the wide opening of the yolk sac, which is gradually narrowed and reduced to a small foramen leading into the vitelline duct. At first the foregut and hindgut end blindly. The anterior end of the foregut is separated from the stomodeum by the buccopharyngeal membrane (Fig. 16-1); the hindgut ends in the cloaca, which is closed by the cloacal membrane.

### MOUTH AND ASSOCIATED STRUCTURES

**MOUTH.** The mouth is developed partly from the stomodeum and partly from the floor of the anterior portion of the foregut. By the growth of the head end of the embryo and the formation of the cephalic flexure, the pericardial area and the buccopharyngeal membrane come to lie on the ventral surface of the embryo. With the further expansion of the brain and the forward bulging of the pericardium, the buccopharyngeal membrane is depressed between these two prominences. This depression constitutes the **stomodeum** (Fig. 16-1), which is lined by ectoderm and is separated from the anterior end of the foregut by the buccopharyngeal membrane. This membrane is devoid of mesoderm, being formed by the apposition of the stomodal ectoderm with the foregut endoderm; at the end of the third week it disappears, and thus a communication is established between the mouth and the future pharynx. No trace of the membrane is found in the adult, and the communication just mentioned must not be confused with the permanent isthmus faucium. The lips, teeth, and gums are formed from the walls of the stomodeum, but the tongue develops in the floor of the pharynx.

The visceral arches extend ventrally between the stomodeum and the pericardium, and with the completion of the mandibular arch and the formation of the maxillary processes, the mouth assumes the appearance of a pentagonal orifice. The orifice is bounded cranially by the frontonasal process, caudally by the mandibular arch, and laterally by the maxillary processes (Fig. 16-2). With the inward growth and fusion of the palatine processes (Figs. 2-55; 2-56), the stomodeum is divided into an upper nasal and a lower buccal part. Along the free margins of the processes bounding the mouth cavity a shallow groove appears; this is

Fig. 16-2. Head end of human embryo about 30 to 31 days old. (From model by Peters.)

termed the **primary labial groove**, and from the bottom of it ectoderm grows downward into the underlying mesoderm. The central cells of the ectodermal downgrowth degenerate and a **secondary labial groove** forms, and as this deepens, the lips and cheeks separate from the alveolar processes of the maxillae and mandible.

**SALIVARY GLANDS.** The salivary glands arise as buds from the epithelial lining of the mouth. The parotid gland appears during the fourth week in the angle between the maxillary process and the mandibular arch. The submandibular gland appears in the sixth week, and the sublingual gland appears during the ninth week in the hollow between the tongue and the mandibular arch.

**TONGUE.** The tongue (Figs. 16-3 to 16-6) develops in the floor of the pharynx, and consists of an anterior or buccal part and a posterior or pharyngeal part, which are separated in the adult by the V-shaped sulcus terminalis. During the third week there appears, immediately dorsal to the ventral ends of the two halves of the mandibular arch, a rounded swelling named the **tuberculum impar**, which may help to form the buccal part of the tongue or may be purely a transitory structure. From the ventral ends of the fourth arch there arises a second and larger elevation, in the center of which is a median groove or furrow. This elevation was

**FIG. 16-3.** Same embryo as shown in Figure 16-2, with front wall of pharynx removed.

named the **furcula** by His<sup>1</sup> and at first it is separated from the tuberculum impar by a depression, but later by a ridge, the **copula**, which is formed by the forward growth and fusion of the ventral ends of the second and third arches. The posterior or pharyngeal part of the tongue develops from the copula, which extends forward in the form of a V, to embrace between its two limbs the buccal part of the tongue. At the apex of the V, a pit-like invagination occurs to form the thyroid gland, and this depression is represented in the adult by the **foramen cecum** of the tongue. In the adult the union of the anterior and posterior parts of the tongue is

<sup>1</sup>Wilhelm His (1831-1904): A German anatomist and physiologist (Basel and Leipzig).

**FIG. 16-4.** Floor of pharynx of human embryo about 26 days old. (From model by Peters.)

**FIG. 16-5.** Floor of pharynx of human embryo at the end of the fourth week. (From model by Peters.)

marked by the V-shaped **sulcus terminalis**, the apex of which is at the foramen cecum, while the two limbs run lateralward and forward, parallel to, but a little behind, the vallate papillae.

**PALATINE TONSILS.** The palatine tonsils develop from the dorsal angles of the second branchial pouches. The entoderm that lines these pouches grows into the surrounding mesoderm in the form of solid buds. These buds become hollowed out by the degeneration and casting off of their central cells, forming the tonsillar crypts. Lymphoid cells accumulate around the crypts and become grouped to form the lymphoid follicles; the latter, however, are not well defined until after birth.

#### PHARYNX AND POSTPHARYNGEAL ALIMENTARY TUBE

The cranial part of the foregut becomes dilated to form the pharynx (Fig. 16-1), in relation to which the branchial arches are developed (see p. 45); the succeeding part re-

**FIG. 16-6.** Floor of pharynx of human embryo about 30 days old. (From model by Peters.)

mains tubular, and with the descent of the stomach is elongated to form the esophagus. About the fourth week a fusiform dilatation appears, which is the future stomach, and beyond this the gut opens freely into the yolk sac (Fig. 16-7, A and B). The opening is wide at first, but it gradually narrows into a tubular stalk, the **yolk stalk** or **vitelline duct**.

Between the stomach and the mouth of the yolk sac the liver diverticulum appears. From the stomach to the rectum the alimentary canal is attached to the notochord by a band of mesoderm, from which the common mesentery of the gut subsequently develops.

The stomach is also attached to the ventral abdominal wall as far as the umbilicus by

FIG. 16-7. Sketches in profile of two stages in the development of the human digestive tube. (His.) A, 30  $\times$ ; B, 20  $\times$ .

the septum transversum. The cranial portion of the septum takes part in the formation of the diaphragm, whereas the caudal portion, into which the liver grows, forms the **ventral mesogastrium** (Fig. 16-10). As the stomach undergoes further dilatation, its two curvatures become recognizable (Figs. 16-7, B; 16-8), the greater curvature oriented toward the vertebral column and the lesser curvature toward the anterior wall of the abdomen, with its two surfaces facing to the right and left respectively. Caudal to the stomach the gut undergoes great elongation and forms a V-shaped loop that projects ventralward; from the bend or angle of the loop the vitelline duct passes into the umbilicus (Fig. 16-9). For a time a large part of the loop extends beyond the abdominal cavity into the umbilical cord, but by the end of the third month it has been drawn back into the cavity. With the lengthening of the tube, the mesoderm that attaches it to the future vertebral column and carries the blood vessels to supply the gut, becomes thinner and drawn out to form the **posterior common mesentery**. The portion of this mesentery that is attached to the greater curvature of the stomach is named the **dorsal mesogastrium**, and the part that suspends the colon is termed the **mesocolon** (Fig. 16-10).

About the sixth week, a diverticulum of the gut appears just caudal to the opening of the vitelline duct and indicates the future

cecum and vermiform appendix. The part of the loop on the distal side of the cecal diverticulum increases in diameter and forms the future ascending and transverse portions of the large intestine. Until the fifth month the cecal diverticulum has a uniform caliber, but from this time onward its distal part remains rudimentary and forms the vermiform appendix, while its proximal part expands to form the cecum. Changes also take place in the shape and position of the stomach. Its dorsal part or greater curvature, to which the dorsal mesogastrium is attached, grows much more rapidly than its ventral part or lesser curvature, to which the ventral mesogastrium is fixed. Also, the greater curvature swings toward the left, so that the right surface of the stomach becomes directed dorsalward and the left surface ventralward (Fig. 16-11), a change in position that explains why the left vagus nerve is found on the ventral surface of the stomach and the right vagus on the dorsal surface. The dorsal mesogastrium, being attached to the greater curvature, must necessarily follow this movement, and hence it becomes greatly elongated and drawn lateralward and ventralward from the vertebral column; as in the case of the stomach, the right surfaces of both the dorsal and ventral mesogastra are now directed dorsalward, and the left ventralward. In this way a pouch, the **lesser sac (omental bursa)**, is

FIG. 16-8. Ventral view of two successive stages in the development of the digestive tube. (His.)

**FIG. 16-9.** The primitive mesentery of a six-week-old human embryo, half schematic. (Kollmann.)

formed dorsal to the stomach. This increases in size as the digestive tube undergoes further development, and the entrance to the pouch becomes the future **epiploic foramen** or **foramen of Winslow**.<sup>1</sup>

The duodenum develops from the part of

<sup>1</sup>Jacob Benignus Winslow (1669-1760): A Danish anatomist who worked in Paris.

the tube that immediately succeeds the stomach; it undergoes little elongation, being more or less fixed in position by the liver and pancreas, which arise as diverticula from it. The duodenum is first suspended by a mesentery and projects ventralward in the form of a loop. The loop and its mesentery are subsequently displaced by the transverse colon, so that the right surface of the duodenal mesentery is directed dorsalward, and adhering to the parietal peritoneum, is lost. The remainder of the digestive tube becomes greatly elongated, and as a consequence the tube is coiled on itself. This elongation demands a corresponding increase in the width of the intestinal attachment of the mesentery, which becomes folded.

At this stage the small and large intestines are attached to the vertebral column by a continuous common mesentery, with the coils of the small intestine falling to the right of the midline and the large intestine falling to the left (Fig. 16-11).

Sometimes this condition persists throughout life, and it is then found that the duodenum does not cross from the right to the left side of the vertebral column, but lies entirely on the right side of the

**FIG. 16-10.** Abdominal part of digestive tube and its attachment to the primitive or common mesentery. Human embryo of six weeks. (After Toldt.)

**Fig. 16-11.** Diagrams to illustrate two stages in the development of the digestive tube and its mesentery. The arrow indicates the entrance to the bursa omentalis. The ventral mesogastrium has been eliminated.

median plane, where it is continued into the jejunum; the arteries to the small intestine also arise from the right instead of the left side of the superior mesenteric artery.

The gut is now rotated counterclockwise upon itself, so that the large intestine is carried ventral to the small intestine, and the cecum is placed immediately caudal to the liver. About the sixth month the cecum descends into the right iliac fossa, and the large intestine forms an arch consisting of the ascending, transverse, and descending portions of the colon; the transverse portion crosses ventral to the duodenum and lies just caudal to the greater curvature of the stomach, the coils of the small intestine being disposed within this arch (Fig. 16-12). Sometimes the caudalward progress of the cecum is arrested, so that in the adult it may lie immediately caudal to the liver instead of in the right iliac region.

Further changes that take place in the lesser sac (omental bursa) and in the common mesentery give rise to the peritoneal relations seen in the adult. The omental bursa, which at first reaches only as far as the greater curvature of the stomach, grows caudalward to form the greater omentum; this extension lies ventral to the transverse colon and the coils of the small intestine (Fig. 16-13). Be-

fore the pleuroperitoneal opening is closed, the omental bursa sends a diverticulum cranialward on either side of the esophagus; the left diverticulum soon disappears, but the right diverticulum becomes constricted

**Fig. 16-12.** Final disposition of the intestines and their vascular relations. (Jonnesco.) A, Aorta. H, Hepatic artery. M, Col., Branches of superior mesenteric artery. m, Branches of inferior mesenteric artery. S, Splenic artery.

**FIG. 16-13.** Schematic figure of the omental bursa, etc. Human embryo of eight weeks. (Kollmann.)

and persists in most adults as a small sac lying within the thorax on the right side of the caudal end of the esophagus.

The ventral layer of the transverse mesocolon is at first distinct from the dorsal layer of the greater omentum, but ultimately the two blend, and hence the greater omentum appears to be attached to the transverse colon (Fig. 16-14). The mesenteries of the ascending and descending parts of the colon disappear in the majority of cases, while that of the small intestine assumes the oblique

attachment characteristic of its adult condition.

The lesser omentum is formed, as indicated previously, by the mesoderm or **ventral mesogastrium**, which attaches the stomach and duodenum to the anterior abdominal wall. The subsequent growth of the liver separates this leaf into two parts: the lesser omentum between the stomach and liver, and the falciform and coronary ligaments between the liver and the abdominal wall and diaphragm (Fig. 16-13).

## RECTUM AND ANAL CANAL

The hindgut is at first prolonged caudalward into the body stalk as the tube of the allantois. With the growth and flexure of the caudal end of the embryo, the body stalk, with its allantoic tube, is carried cranialward to the ventral aspect of the body, and consequently a bend is formed at the junction of the hindgut and allantois. This bend becomes dilated into a pouch that constitutes the **entodermal cloaca**; the hindgut opens into its dorsal part and the allantois extends out ventrally from its ventral part. At a later stage the mesonephric (Wolffian)<sup>1</sup> and paramesonephric (Müllerian)<sup>2</sup> ducts open into its ventral portion. The cloaca is, for a time,

<sup>1</sup>Kaspar Friedrich Wolff (1733-1794): A Russian anatomist and physiologist (St. Petersburg).

<sup>2</sup>Johannes Peter Müller (1801-1858): A German anatomist and physiologist (Berlin).

**FIG. 16-14.** Diagrams to illustrate the development of the greater omentum and transverse mesocolon.

shut off from the exterior by the **cloacal membrane**, which is formed by the apposition of the ectoderm and entoderm and reaches, at first, as far cranialward as the future umbilicus. The mesoderm subsequently progresses caudalward to form the lower part of the abdominal wall and symphysis pubis. By the growth of the surrounding tissues, the cloacal membrane comes to lie at the bottom of a depression, which is lined by ectoderm and is named the **ectodermal cloaca** (Fig. 16-15).

The entodermal cloaca is divided into a dorsal and a ventral part by means of a partition, the **urorectal septum** (Fig. 16-16), which grows caudalward from the ridge that separates the allantoic from the cloacal opening of the intestine; ultimately, this septum fuses with the cloacal membrane and divides it into an anal and a urogenital part. The dorsal part of the cloaca forms the rectum, and the ventral part forms the urogenital sinus and bladder. For a time a communication named the **cloacal duct** exists between the two parts of the cloaca below the urorectal septum; this duct occasionally persists as a passage between the rectum and urethra.

The anal canal is formed by an invagination of the ectoderm behind the urorectal septum. This invagination is termed the **proctodeum**, and it meets with the entoderm of the hindgut and forms the **anal membrane**. By the absorption of this membrane, the anal canal becomes continuous with the rectum (Fig. 17-12). A small part of the hindgut projects caudalward beyond the anal membrane; it is named the **postanal gut** (Fig. 16-15), and it usually becomes obliterated.

**Fig. 16-15.** Tail end of human embryo 15 to 18 days old. (From model by Keibel.)

**Fig. 16-16.** Cloaca of human embryo 25 to 27 days old. (From model by Keibel.)

## The Mouth

The **cavity of the mouth** (oral or buccal cavity) (Fig. 16-17) is placed at the commencement of the digestive tube; it is a nearly oval shaped cavity that consists of two parts: an outer, smaller portion, the **vestibule**, and an inner, larger part, the **mouth cavity proper**.

### VESTIBULE

The vestibule (*vestibulum oris*) is a slitlike space, bounded externally by the lips and cheeks, internally by the gums and teeth. It communicates with the surface of the body by the **rima or orifice of the mouth**. Superiorly and inferiorly, it is limited by the reflection of the mucous membrane from the lips and cheeks to the gums covering the upper and lower alveolar arches respectively. It receives the secretion from the parotid salivary glands and communicates, when the jaws are closed, with the mouth cavity proper by an aperture on either side behind the molar teeth and by narrow clefts between opposing teeth.

### MOUTH CAVITY PROPER

The mouth cavity proper (Fig. 16-17) is bounded laterally and ventrally by the alveolar arches with their contained teeth; dorsally, it communicates with the pharynx by a constricted aperture termed the **isthmus**

**FIG. 16-17.** Median sagittal section of head and neck showing nasal, pharyngeal, and laryngeal cavities. (Eycleshymer and Jones.)

**faucium.** It is roofed in by the hard and soft palates, while the greater part of the floor is formed by the tongue, the remainder by the reflection of the mucous membrane from the sides and under surface of the tongue to the gum lining the inner aspect of the mandible. It receives the secretions from the submandibular and sublingual salivary glands.

## LIPS

The lips (*labia oris*) (Fig. 16-17), the two fleshy folds that surround the rima or orifice of the mouth, are covered externally by integument and internally by mucous membrane, between which are found the orbicularis oris muscle, the labial vessels, some

nerves, areolar tissue, fat, and numerous small labial glands. The inner surface of each lip is connected in the midline to the corresponding gum by a median fold of mucous membrane, the **frenulum**.

The **labial glands** are situated between the mucous membrane and the orbicularis oris, around the orifice of the mouth. They are globular and about the size of small peas; their ducts open by minute orifices upon the mucous membrane. In structure they resemble the salivary glands.

## CHEEKS

The cheeks (*buccae*) form the sides of the face and are continuous anteriorly with the lips. They are composed externally of integument and internally of mucous membrane; between the two are a muscular stratum, a large quantity of fat (*corpus adiposum buccae*), areolar tissue, vessels, nerves, and buccal glands.

The **buccal glands** are placed between the mucous membrane and buccinator muscle; they are similar in structure to the labial glands but smaller. About five glands, larger than the rest, are placed between the masseter and buccinator muscles around the distal extremity of the parotid duct; their ducts open in the mouth opposite the last molar tooth. They are called **molar glands**.

**STRUCTURE OF THE CHEEKS.** The **mucous membrane** lining the cheek is reflected above and below upon the gums, and is continuous behind with the lining membrane of the soft palate. Opposite the second molar tooth of the maxilla is a papilla, on the summit of which is the aperture of the parotid duct (*papilla parotideae*). The principal muscle of the cheek is the buccinator, but other muscles enter into its formation, viz., the zygomaticus, risorius, and the platysma muscles.

## GUMS

The gums (*gingivae*) are composed of dense fibrous tissue that is closely connected to the periosteum of the alveolar processes and surrounds the necks of the teeth. They are covered by a smooth and vascular mucous membrane, which is remarkable for its

limited sensibility. Around the necks of the teeth this membrane presents numerous fine papillae and is reflected into the alveoli, where it is continuous with the periosteal membrane lining these cavities.

## PALATE

The palate forms the roof of the mouth. It consists of two portions, the **hard palate** anteriorly and the **soft palate** posteriorly.

**HARD PALATE.** The hard palate (*palatum durum*) (Fig. 16-17) forms the roof of the mouth and separates the oral and nasal cavities. It is bounded anteriorly and at the sides by the alveolar arches and gums; posteriorly, it is continuous with the soft palate. Its bony support (*palatum osseum*), formed by the palatine process of the maxilla and the horizontal part of the palatine bone (Fig. 16-19), is covered by a dense structure formed by the periosteum and mucous membrane of the mouth, which are intimately adherent. Along the midline is a linear raphe, which ends anteriorly in a small papilla (*papilla incisiva*) that corresponds with the incisive canal. On either side and anterior to the raphe, the mucous membrane is thick, pale, and corrugated; posteriorly, it is thin, smooth, and of a deeper color. It is covered with stratified squamous epithelium and furnished with numerous palatal glands that lie between the mucous membrane and the surface of the bone.

**SOFT PALATE.** The soft palate (*palatum molle*) (Fig. 16-17) is suspended from the posterior border of the hard palate. It consists of a fold of mucous membrane that encloses muscular fibers, an aponeurosis, vessels, nerves, lymphoid tissue, and mucous glands. When elevated, as in swallowing and in sucking, it completely separates the nasal cavity and nasopharynx from the posterior part of the oral cavity and the oral portion of the pharynx (Fig. 16-17). When occupying its usual position, i.e., relaxed and pendent, its anterior surface is concave, continuous with the roof of the mouth, and marked by a median raphe. Its posterior surface is convex and continuous with the mucous membrane that covers the floor of the nasal cavities. It is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its posterior border, termed the

**palatine velum** (*velum palatinum*), is free and hangs like a curtain between the mouth and pharynx.

Hanging from the middle of its posterior border is a small, conical, pendulous process, the **palatine uvula**. Arching lateralward from the base of the uvula on either side are two curved folds of mucous membrane that contain muscular fibers and are called the **arches** or **pillars of the fauces** (Fig. 16-42).

## The Teeth

16-24) appear at different periods of life. Those of the first set appear in infancy and are called the **deciduous** or **milk teeth**. Those of the second set appear in childhood, persist until old age, and are named **permanent teeth**.

The **deciduous teeth** number 20: four incisors, two canines, and four molars in each jaw. The **permanent teeth** number 32: four incisors, two canines, four premolars, and six molars in each jaw. The **dental formulae** may be represented as shown in Table 16-1.

## GENERAL CHARACTERISTICS

Each tooth consists of three portions: the **crown**, projecting from the gum; the **root**, embedded in the alveolus; and the **neck**, the constricted portion between the crown and root (Fig. 16-24).

The **roots** of the teeth are firmly implanted in depressions within the alveoli; these depressions are lined with periosteum, which invests each tooth as far as the neck. At the margins of the alveoli, the periosteum is con-

**FIG. 16-18.** Side view of the teeth and jaws.

FIG. 16-19. Permanent teeth of upper dental arch, seen from below.

FIG. 16-20. Permanent teeth of right half of lower dental arch, seen from above.

tinuous with the fibrous structure of the gums.

Because of the curve of the dental arch, terms such as anterior and posterior, as applied to the teeth, are misleading and confusing. Special terms are therefore used to indicate the different surfaces of a tooth: the surface directed toward the lips or cheek is known as the **labial** or **buccal surface**; that directed toward the tongue is described as the **lingual surface**; those that touch neighboring teeth are termed **surfaces of contact**. In the case of the incisor and canine teeth, the surfaces of contact are medial and lateral; in the premolar and molar teeth they are anterior and posterior.

The superior dental arch is larger than the inferior, so that in the normal condition the teeth in the maxillae slightly overlap those of the mandible both anteriorly and at the sides. Since the upper central incisors are wider than the lower, the other teeth in the upper arch are thrown somewhat posteriorly, and the two sets do not quite correspond to each other when the mouth is closed. Thus the upper canine tooth rests partly on the lower canine and partly on the first premolar, and the cusps of the upper

FIG. 16-21. Permanent teeth. Right side. (Burchard.)

molar teeth lie behind the corresponding cusps of the lower molar teeth. The two series, however, end at nearly the same point posteriorly, mainly because the molars in the upper arch are smaller than those in the lower arch.

#### PERMANENT TEETH (FIGS. 16-20; 16-21)

**INCISORS.** The incisors are so named for their sharp cutting edge, which is adapted for biting food. There are eight, and they form the four front teeth in each dental arch.

FIG. 16-22. The permanent teeth, viewed from the right. The external layer of bone has been partly removed and the maxillary sinus has been opened to show the blood and nerve supply to the teeth. (Eycleshymer and Jones.)

FIG. 16-23. Deciduous teeth. Left side.

The **crown** of each incisor is directed vertically and is chisel-shaped, being bevelled at the expense of its lingual surface, so that it has a sharp horizontal cutting edge, which, before being subjected to attrition, presents three small prominent points separated by

two slight notches. It is convex, smooth, and highly polished on its labial surface and concave on its lingual surface, where, in the teeth of the upper arch, it is frequently marked by an inverted V-shaped eminence situated near the gum. This is known as the **basal ridge** or **cingulum**. The **neck** is constricted. The **root** is long, single, conical, transversely flattened, thicker anteriorly, and slightly grooved on either side in the longitudinal direction.

The **upper incisors** are larger and stronger than the lower and are directed obliquely downward and forward. The central incisors are larger than the lateral incisors and their roots are more rounded.

The **lower incisors** are smaller than the upper; the central ones are smaller than the lateral and are the smallest of all the incisors. They are placed vertically and are somewhat bevelled anteriorly, where they

FIG. 16-24. Diagrammatic representation of the dental tissue. (Schour, Noyes' *Oral Histology and Embryology*.)

have been worn down by contact with the overlapping edge of the upper teeth. The cingulum is absent.

**CANINE TEETH.** There are four canine teeth: two in the upper and two in the lower arch; one is placed lateral to each lateral incisor. They are larger and stronger than the incisors. Their roots sink deeply into the bones and cause well-marked prominences upon the surface of the alveolar arch.

The **crown** is large and conical, very convex on its labial surface, a little hollowed and uneven on its lingual surface, and tapering to a blunted point or cusp that projects beyond the level of the other teeth. The **root** is single but longer and thicker than that of the incisors. It is conical, compressed laterally, and marked by a slight groove on each side.

The **upper canine teeth** (popularly called *eye teeth*) are larger and longer than the lower, and usually present a distinct basal ridge.

The **lower canine teeth** (popularly called *stomach teeth*) are placed nearer the midline than the upper canines, so their summits correspond to the intervals between the upper canines and the lateral incisors.

**PREMOLARS.** There are eight premolar or **bicuspid** teeth: four in each arch. They are situated lateral and posterior to the canine teeth, and are smaller and shorter than the canine teeth.

The **crown** is compressed anteroposteriorly and is surmounted by two pyramidal eminences or cusps, a labial and a lingual, separated by a groove; hence their name **bicuspid**. Of the two cusps the labial is the larger and more prominent. The **neck** is oval. The **root** is generally single, compressed, and presents a deep groove anteriorly and posteriorly, which indicates a tendency in the root to become double. The apex is generally bifid.

The **upper premolars** are larger and have a greater tendency to form divided roots than the lower premolars; this is especially the case for the first upper premolar.

**MOLARS.** The molar teeth are the largest of the permanent set, and their broad crowns are adapted for grinding and crushing food. There are 12 molars: six in each arch, three being placed posterior to the second premolars on each side.

The **crown** of each is nearly cubical, con-

vex on its buccal and lingual surfaces, and flat on its surfaces of contact; it is surmounted by four or five tubercles or cusps, which are separated from each other by a cruciate depression. Hence the molars are sometimes called **multicuspids**. The **neck** is distinct, large, and round.

As a rule, the first of the **upper molars** is the largest and the third is the smallest. The crown of the first has usually four tubercles; that of the second, three or four; that of the third, three. Each upper molar has three roots, and of these two are buccal and nearly parallel to each other; the third is lingual and diverges from the others. The roots of the third molar (*dens serotinus* or *wisdom tooth*) are more or less fused together.

The **lower molars** are larger than the upper. The crown of the first usually has five tubercles; those of the second and third have four or five. Each lower molar has two roots: an anterior, nearly vertical, and a posterior, directed obliquely backward. Both roots are grooved longitudinally, indicating a tendency to divide. The two roots of the third molar (*dens serotinus* or *wisdom tooth*) are more or less united.

## DECIDUOUS TEETH

The deciduous teeth (*temporary* or *milk teeth*) (Fig. 16-23) are smaller than, but generally resemble in form, the permanent teeth that bear the same names. The posterior of the two molars is the largest of all the deciduous teeth, and is succeeded by the first molar. The first upper molar has only three cusps—two labial, one lingual; the second upper molar has four cusps. The first lower molar has four cusps; the second lower molar has five. The roots of the deciduous molars are smaller and more divergent than those of the permanent molars, but in other respects bear a strong resemblance to them.

## STRUCTURE OF THE TEETH

In a vertical section of a tooth (Figs. 16-24 to 16-26), the **pulp cavity** is seen in the interior of the crown and the center of each root; it opens by a minute orifice at the extremity of the latter. It contains the **dental pulp**, a loose connective tissue richly supplied with

FIG. 16-25. Vertical section of a molar tooth.

vessels and nerves, which enter the cavity through the small aperture, the **apical foramen**, at the point of each root. Some of the cells of the pulp are arranged as a layer on the wall of the pulp cavity; these are named the **odontoblasts**, and during the development of the tooth, they are columnar, but later, after the dentin is fully formed, they become flattened and resemble osteoblasts. Each has two fine processes; the outer one passes into a dental canaliculus, the inner one is continuous with the processes of the connective tissue cells of the pulp matrix.

The solid portion of the tooth consists of (1) the **ivory** or **dentin**, which forms the bulk of the tooth; (2) the **enamel**, which covers the exposed part of the crown; and (3) a thin layer of bone, the **cement** or **crusta petrosa**, which is disposed on the surface of the root.

FIG. 16-26. Vertical section of a premolar tooth. (Magnified.)

## Dentin

The **dentin** (*dentinum*; *substantia eburnea*; ivory) (Fig. 16-24) forms the principal mass of a tooth. It is a modification of osseous tissue, from which it differs, however, in structure. Microscopically it consists of a number of minute wavy and branching tubes, the **dental canaliculi**, embedded in a dense homogeneous substance, the **matrix**.

**DENTAL CANALICULI.** The dental canaliculi (*dental tubules*) (Fig. 16-27) are placed parallel with one another and open at their inner ends into the pulp cavity. In their course to the periphery they have two or three curves and twist spirally on themselves. These canaliculi vary in direction: thus in a tooth of the mandible they are vertical in the upper portion of the crown, becoming oblique and then horizontal in the neck and upper part of the root, while toward the lower part of the root they are inclined downward. In their course they divide and subdivide dichotomously, and especially in the root, give off minute branches that join together in loops in the matrix or end blindly. Near the periphery of the dentin, the finer ramifications of the canaliculi terminate imperceptibly by free ends. The dental canaliculi have definite walls, consisting of an elastic homogeneous membrane, the **dentinal sheath** (of Neumann<sup>1</sup>), which resists the action of acids; they contain slender cylindrical prolongations of the odontoblasts, the **dentinal fibers** (Tomes' fibers<sup>2</sup>).

**MATRIX.** The matrix (*intertubular dentin*) is translucent and contains the chief part of the inorganic matter of the dentin. In it are a number of fine fibrils, which are continuous with the fibrils of the dental pulp. After the organic matter has been removed by steeping a tooth in weak acid, the remaining organic matter may be torn into laminae that run parallel with the pulp cavity across the direction of the tubes.

A section of dry dentin often displays a series of somewhat parallel lines—the **incremental lines** (of Salter<sup>3</sup>). These lines are

<sup>1</sup>Ernst N. Neumann (1834-1918): A German pathologist (Königsberg).

<sup>2</sup>Sir John Tomes (1815-1895): An English dental surgeon (London).

<sup>3</sup>Sir Samuel A. Salter (1825-1897): An English dental surgeon and physician (London).

FIG. 16-27. Transverse section of a portion of the root of a canine tooth. 300  $\times$ .

composed of imperfectly calcified dentin arranged in layers. Because of the imperfection in the calcifying process, little irregular cavities are left, termed **interglobular spaces** (Fig. 16-27). Normally a series of these spaces is found toward the outer surface of the dentin, where they form a layer that is sometimes known as the **granular layer**. The name of these spaces was derived from the fact that they are surrounded by minute nodules or globules of dentin.

Other curved lines may be seen parallel to the surface. These are the *lines of Schreger*<sup>1</sup> and are caused by the optical effect of simultaneous curvature of the dentinal fibers.

### Enamel

The enamel (*substantia adamantina*) is the hardest and most compact part of the tooth; it forms a thin crust over the exposed part of the crown as far as the commencement of the root. It is thickest on the grinding surface of the crown (until worn away by

attrition) and becomes thinner toward the neck.

It consists of minute hexagonal rods or columns termed **enamel fibers** or **enamel prisms** (*prismata adamantina*). They lie parallel with one another, resting by one extremity upon the dentin, which has a number of minute depressions for their reception, and forming the free surface of the crown by the other extremity. The columns are directed vertically on the summit of the crown and horizontally at the sides; they are about 4  $\mu$  in diameter, and pursue a more or less wavy course. Each column is a six-sided prism and has numerous dark transverse shadings; these shadings are probably due to the manner in which the columns are developed in successive stages, producing shallow constrictions (as will be subsequently explained).

Another series of lines, which appear brown, the **parallel striae** or **colored lines** (of Retzius<sup>2</sup>), is seen on section. Some believe that these striae are produced by air in the interprismatic spaces; others believe that they are the result of true pigmentation. Numerous minute interstices appear among the enamel fibers near their dentinal ends, a provision calculated to allow the permeation of fluids from the dental canaliculi into the substance of the enamel.

### Cement

The cement or **crusta petrosa** (*substantia ossea*) is disposed as a thin layer on the roots of the teeth from the termination of the enamel to the apex of each root, where it is usually very thick. In structure and chemical composition it resembles bone. It contains, sparingly, the lacunae and canaliculi that characterize true bone. The lacunae placed near the surface receive the canaliculi radiating from the sides of the lacunae toward the periodontal membrane, and those more deeply placed join with the adjacent dental canaliculi. In the thicker portions of the cement, the lamellae and Haversian canals<sup>3</sup> peculiar to bone are also found.

As age advances, the cement increases in thickness and gives rise to those bony

<sup>1</sup>Bernhard Nathaniel von Schreger (1766–1825): A German anatomist and surgeon (Altdorf).

<sup>2</sup>Magnus Gustav Retzius (1842–1919): A Swedish anatomist (Stockholm).

<sup>3</sup>Clopton Havers (1657–1702): An English physician (London).

growths or exostoses so common on the teeth of the aged; the pulp cavity also becomes partially filled with a hard substance that is intermediate in structure between dentin and bone (osteodentin; secondary dentin). It appears to be formed by a slow conversion of the dental pulp, which shrinks or even disappears.

### DEVELOPMENT OF THE TEETH

In describing the development of the teeth, the mode of formation of the deciduous teeth must first be considered, and then that of the permanent series (Figs. 16-28 to 16-31).

#### *Development of the Deciduous Teeth*

The development of the deciduous teeth begins about the sixth week of fetal life as a thickening of the epithelium along the line of the future jaw, the thickening being due to a rapid multiplication of the more deeply situated epithelial cells. As the cells multiply they extend into the subjacent mesoderm, and thus form a ridge or strand of cells embedded in mesoderm.

About the seventh week a longitudinal splitting or cleavage of this strand of cells takes place, and it becomes divided into two strands; the separation begins anteriorly and extends laterally, the process occupying four or five weeks. Of the two strands thus formed, the **labial** forms the **labiodental lamina**, while the other, the **lingual**, is the ridge of cells in which the teeth, both deciduous

and permanent, develop. Hence it is known as the **dental lamina** or **common dental germ**. It forms a flat band of cells that grows into the substance of the embryonic jaw, at first horizontally inward, and then, as the teeth develop, vertically, i.e., upward in the upper jaw and downward in the lower jaw. While still maintaining a horizontal direction it has two edges—an *attached edge*, continuous with the epithelium lining the mouth, and a *free edge*, projecting inward, and embedded in the mesodermal tissue of the embryonic jaw. Along its line of attachment to the buccal epithelium is a shallow groove, the **dental furrow**.

About the ninth week, the dental lamina begins to develop ten enlargements along its free border in each jaw, and each corresponds to a future deciduous tooth. These enlargements consist of masses of epithelial cells, and the cells of the deeper part—that is, the part farthest from the margin of the jaw—increase rapidly and spread out in all directions. Each mass thus comes to assume a club shape, connected with the general epithelial lining of the mouth by a narrow neck and embraced by mesoderm. They are now known as **special dental germs** (Fig. 16-28). After a time the lower expanded portion inclines outward, forming an angle with the superficial constricted portion, which is sometimes known as the neck of the special dental germ.

About the tenth week the mesodermal tissue deep to these special dental germs becomes differentiated into papillae; these grow upward, and come in contact with the

**Fig. 16-28.** Sagittal section through the first lower deciduous molar of a human embryo 30-mm long. (Röse.) 100 ×. L.E.L., Labiodental lamina, here separated from the dental lamina. Z.L., Placed over the shallow dental furrow, points to the dental lamina, which is spread out below to form the enamel germ of the future tooth. P.p., Bicuspid papilla, capped by the enamel germ. Z.S., Condensed tissue forming dental sac. M.E., Mouth epithelium.

**Fig. 16-29.** Similar section through the canine tooth of an embryo 40-mm long. (Röse.) 100  $\times$ . L.F., Labiodental furrow. (Other abbreviations as in Fig. 16-28.)

epithelial cells of the special dental germs, which fold over them like a hood or cap. There is, then, at this stage a papilla (or papillae) that has already begun to assume somewhat the shape of the crown of the future tooth, and from which the dentin and pulp of the tooth are formed, surmounted by

a dome or cap of epithelial cells from which the enamel is derived.

In the meantime, while these changes have been going on, the dental lamina has been extending posteriorly behind the special dental germ corresponding to the second deciduous molar tooth, and at about the seventeenth week it presents an enlargement, the special dental germ for the first permanent molar, soon followed by the formation of a papilla in the mesodermal tissue for the same tooth. This is followed, about the sixth month after birth, by a further extension posteriorly of the dental lamina, with the formation of another enlargement and its corresponding papilla for the second molar. And finally the process is repeated for the third molar, its papilla appearing about the fifth year of life.

After the formation of the special dental germs, the dental lamina undergoes atrophic changes and becomes cribriform, except on the lingual and lateral aspects of each of the special germs of the temporary teeth, where it undergoes a local thickening to form the special dental germ of each of the successional permanent teeth—i.e., the ten anterior ones in each jaw. Here the same process goes on as has been described in connection with those of the deciduous teeth: that is, the special dental germs recede into the substance of the gum behind the germs of the deciduous teeth. As they recede they become club-shaped, form expansions at their distal extremities, and finally meet papillae, which have been formed in the mesoderm, in the same manner as was the case in the decidu-

**Fig. 16-30.** Longitudinal section of the lower part of a growing tooth, showing the extension of the layer of ameloblasts beyond the crown to mark off the limit of formation of the dentin of the root. (Röse.) am., Ameloblasts, continuous below with ep. sch., the epithelial sheath of Hertwig. d., Dentin. en., Enamel. od., Odontoblasts. p., Pulp.

FIG. 16-31. Vertical section of the mandible of an early human fetus. 25  $\times$ .

ous teeth. The apex of each papilla indents the dental germ, which encloses it, and forming a cap for it, becomes converted into the enamel, while the papilla forms the dentin and pulp of the permanent tooth.

The **special dental germs** consist at first of rounded or polyhedral epithelial cells; after the formation of the papillae, these cells undergo a differentiation into three layers. Those in immediate contact with the papilla become elongated and form a layer of well-marked columnar epithelium that coats the papilla. They are the cells that form the enamel fibers, and are therefore termed **enamel cells** or **ameloblasts** (Fig. 16-30). The cells of the outer layer of the special dental germ, which are in contact with the inner surface of the dental sac (presently to be described), are much shorter, cubical, and are named the **external enamel epithelium**. All the intermediate round cells of the dental germ between these two layers undergo a peculiar change. They become stellate and develop processes that unite to form a network into which fluid is secreted; this has the appearance of a jelly, and to it the name of enamel pulp is given. This transformed special dental germ is now known by the name of **enamel organ** (Fig. 16-31).

While these changes are occurring, a sac is formed around each enamel organ from the surrounding mesodermal tissue. This is known as the **dental sac**, and it is a vascular membrane of connective tissue. It grows up from below, and thus encloses the whole

tooth germ. As it grows it causes the neck of the enamel organ to atrophy and disappear, so that all communication between the enamel organ and the superficial epithelium is cut off. At this stage there are vascular papillae surmounted by caps of epithelial cells, the whole being surrounded by membranous sacs.

**FORMATION OF THE ENAMEL** (Fig. 16-30). The enamel is formed exclusively from the enamel cells or ameloblasts of the special dental germ, either by direct calcification of the columnar cells, which become elongated into the hexagonal rods of the enamel, or, as is more generally believed, as a secretion from the ameloblasts within which calcareous matter is subsequently deposited.

The process begins at the apex of each cusp, at the ends of the enamel cells in contact with the dental papilla. Here a fine globular deposit appears, apparently being shed from the end of the ameloblasts. It is known as the **enamel droplet**, and it resembles keratin in its resistance to the action of mineral acids. This droplet then becomes fibrous, calcifies, and forms the first layer of enamel; a second droplet now appears and calcifies, and so on; successive droplets of this keratin-like material are shed from the ameloblasts and form successive layers of enamel, the ameloblasts gradually receding as each layer is produced, until at the termination of the process they have almost disappeared.

The intermediate cells of the enamel pulp

atrophy and disappear, so that the newly formed calcified material and the external enamel epithelium come into apposition. This latter layer, however, soon disappears on the emergence of the tooth beyond the gum. After its disappearance, the crown of the tooth is still covered by a distinct membrane, which persists for some time. This is known as the **cuticula dentis**, or **Nasmyth's membrane**,<sup>1</sup> and is believed to be the last-formed layer of enamel derived from the ameloblasts, which has not become calcified. It forms a horny layer, which may be separated from the subjacent calcified mass by the action of strong acids. It is marked by the hexagonal impressions of the enamel prisms, and when stained by silver nitrate, shows the characteristic appearance of epithelium.

**FORMATION OF THE DENTIN** (Fig. 16-30). While these changes take place in the epithelium to form the enamel, contemporaneous changes in the differentiated mesoderm of the dental papillae result in the formation of the dentin. As stated before, the first germs of the dentin are the papillae, which correspond in number to the teeth and are formed from the soft mesodermal tissue that bounds the depressions containing the special enamel germs.

The papillae grow upward into the enamel germs and become covered by them; both are enclosed in a vascular connective tissue, the **dental sac**, in the manner described previously. Each papilla then constitutes the formative pulp from which the dentin and permanent pulp are developed; it consists of round cells and is highly vascular, and soon begins to assume the shape of the future tooth. The next step is the appearance of the **odontoblasts**, whose relation to the development of the teeth is similar to that of osteoblasts to the formation of bone. They are formed from the cells of the periphery of the papilla—that is, from the cells in immediate contact with the ameloblasts of the special dental germ. These cells become elongated; one end of the elongated cell rests against the epithelium of the special dental germs, and the other end is tapered and often branched.

By direct transformation of the peripheral ends of these cells, or by a secretion from

them, a layer of uncalcified matrix (**prodentin**) is formed that caps the cusp or cusps of the papillae. This matrix becomes fibrillated, and in it islets of calcification appear and coalesce to form a continuous layer of calcified material that covers each cusp and constitutes the first layer of dentin. The odontoblasts, having thus formed the first layer, retire toward the center of the papilla, and as they do so, they produce successive layers of dentin from their peripheral extremities, i.e., they form the dentinal matrix in which calcification subsequently occurs.

As they thus recede from the periphery of the papilla, the odontoblasts leave behind filamentous processes of protoplasm, which are provided with finer side processes. These are surrounded by the calcified material and thus form the dental canaliculi, and, by their side branches, the anastomosing canaliculi. The processes of protoplasm contained within them constitute the **dentinal fibers** (Tomes' fibers).

In this way the entire thickness of the dentin is developed, each canaliculus being completed throughout its whole length by a single odontoblast. The central part of the papilla does not undergo calcification, but persists as the pulp of the tooth. In this process of dentin formation, an uncalcified matrix is first developed, and in this matrix islets of calcification appear, which subsequently blend together to form a cap to each cusp; in like manner, successive layers are produced, which ultimately become blended with each other. In certain places this blending is not complete, and portions of the matrix remain uncalcified between the successive layers; this gives rise to little spaces, which are the interglobular spaces alluded to previously.

**FORMATION OF THE CEMENT.** The root of the tooth begins to form shortly before the crown emerges through the gum but is not completed until some time afterward. It is produced by a downgrowth of the epithelium of the dental germ, which extends almost as far as the location of the apex of the future root and determines the form of this portion of the tooth. This fold of epithelium is known as the **epithelial sheath**, and on its papillary surface odontoblasts appear, which in turn form dentin, so that the process of dentin formation is identical in both the crown and the root. After the dentin of the root has developed, the vascular tissues

<sup>1</sup>Alexander Nasmyth (d. 1847): A Scottish dental surgeon (London).

of the dental sac break through the epithelial sheath and spread over the surface of the root as a layer of bone-forming material. Osteoblasts appear in this material, and the process of ossification is identical to the ordinary intramembranous ossification of bone. In this way the cement is formed, which consists of ordinary bone containing canaliculi and lacunae.

**FORMATION OF THE ALVEOLI.** About the fourteenth week of embryonic life, the dental lamina becomes enclosed in a trough or groove of mesodermal tissue, which at first is common to all the dental germs, but subsequently becomes divided by bony septa into loculi. Each loculus contains the special dental germ of a deciduous tooth and its corresponding permanent tooth. After birth, each cavity becomes subdivided, so as to form separate loculi (the future alveoli) for each deciduous tooth and for its corresponding permanent tooth. Although at one time the whole of the growing tooth is contained in the cavity of the alveolus, the latter never completely encloses it, since there is always an aperture over the top of the crown that is filled by soft tissue, by which the dental sac is connected with the surface of the gum, and which in the permanent teeth is called the **gubernaculum dentis**.

#### **Development of the Permanent Teeth**

The permanent teeth develop in two sets: (1) those that replace the deciduous teeth, and which, like them, number ten in each jaw: these are the **successional permanent teeth**; and (2) those that have no deciduous predecessors, but are added to the temporary dental series. There are three such teeth on either side in each jaw, and they are called **superadded permanent teeth**. These include the three molars of the permanent set, as the molars of the deciduous set are replaced by the premolars of the permanent set. The development of the successional permanent teeth—the ten anterior ones in either jaw—has already been indicated. During their development the permanent teeth, enclosed in their sacs, come to lie on the lingual side of the deciduous teeth, more distant from the margin of the future gum, and as already stated, are separated from the deciduous teeth by bony partitions. As the crown of the permanent tooth grows, these bony partitions and the root of the decidu-

ous tooth are absorbed, and finally nothing but the crown of the deciduous tooth remains. This is shed or removed and the permanent tooth takes its place.

The superadded permanent teeth develop in the manner already described, by extensions of the posterior part of the dental lamina in each jaw.

#### **ERUPTION OF THE TEETH (FIGS. 16-32; 16-33)**

When the calcification of the different tissues of the tooth is sufficiently advanced to enable it to bear the pressure to which it will be afterward subjected, eruption occurs with the tooth making its way through the gum. The gum is absorbed by the pressure of the crown of the tooth against it, which is itself pressed toward the surface by the increasing size of the root. At the same time the septa between the dental sacs ossify and constitute the alveoli; these firmly embrace the necks of the teeth and afford them a solid basis of support.

The eruption of the deciduous teeth commences about the seventh month after birth and is complete about the end of the second year. The teeth of the lower jaw erupt before those of the upper jaw.

The following are the most usual times of eruption:

Lower central incisors . . . .	6 to 9 months
Upper incisors . . . . .	8 to 10 months
Lower lateral incisors and	
first molars . . . . .	15 to 21 months
Canines . . . . .	16 to 20 months
Second molars . . . . .	20 to 24 months

There are, however, considerable variations in these times. Thus, according to Holt, at the age of 1 year, a child should have 6 teeth; at 1½ years, 12 teeth; at 2 years, 16 teeth; and at 2½ years, 20 teeth.

Calcification of the permanent teeth proceeds in the following order in the lower jaw (in the upper jaw it occurs a little later): the first molar, soon after birth; the central and lateral incisors and the canine, about six months after birth; the premolars, at the second year or a little later; the second molar, about the end of the second year; the third molar, about the twelfth year.

The eruption of the permanent teeth takes

**Fig. 16-32.** Maxilla and mandible at about one year. (Noyes.)

place at the following periods, the teeth of the lower jaw preceding those of the upper by short intervals:

First molars . . . . .	.6th year
Two central incisors . . . . .	.7th year
Two lateral incisors . . . . .	.8th year
First premolars . . . . .	.9th year
Second premolars . . . . .	.10th year
Canines . . . . .	.11th to 12th year
Second molars . . . . .	.12th to 13th year
Third molars . . . . .	.17th to 25th year

Toward the sixth year, before the shedding of the deciduous teeth begins, there are 24 teeth in each jaw: the ten deciduous teeth and the crowns of all the permanent teeth except the third molars (Fig. 16-33). The third molars (*wisdom teeth*; *dentes serotini*) are irregular in their eruption and may be badly oriented or buried in bone to such an extent that they must be removed surgically. Not infrequently, one or all four may fail entirely to develop.

## The Tongue

The **tongue** (*lingua*) is the principal organ of the sense of taste and an important organ of speech; it also assists in the mastication and deglutition of food. It is situated in the floor of the mouth, within the curve of the body of the mandible.

### BORDERS AND SURFACES

**ROOT.** The root (*base*) is the posterior part of the tongue and it is connected with the hyoid bone by the hyoglossus and genio-glossus muscles and the hyoglossal membrane; with the epiglottis by three folds (*glossoepiglottic folds*) of mucous mem-

**Fig. 16-33.** The teeth of a child aged about seven years. The permanent teeth are colored blue.

brane; with the soft palate by the glossopalatine arches; and with the pharynx by the superior constrictor muscle of the pharynx and the mucous membrane.

**APEX.** The apex (tip) is the somewhat attenuated anterior end, which rests against the lingual surfaces of the lower incisor teeth.

**INFERIOR SURFACE.** The inferior surface (undersurface) (Fig. 16-39) is connected with the mandible by the mucous membrane, which is reflected over the floor of the mouth to the lingual surface of the gum. The mu-

cous membrane between the floor and the tongue in the midline is elevated into a distinct vertical fold, the **frenulum linguae**. On either side lateral to the frenulum is a slight fold of the mucous membrane, the **plica fimbriata**, the free edge of which occasionally exhibits a series of fringe-like processes.

The apex of the tongue, part of the inferior surface, the sides, and the dorsum are free.

**DORSUM.** The dorsum of the tongue (Fig. 16-34) is convex and marked by a **median sulcus**, which divides it into symmetrical halves. This sulcus ends posteriorly about

FIG. 16-34. The dorsum of the tongue.

2.5 cm from the root of the organ in a depression called the **foramen cecum**, from which a shallow groove, the **sulcus terminalis**, runs lateralward and forward on either side to the margin of the tongue. The part of the dorsum of the tongue that is anterior to this groove, forming about two-thirds of its surface, is rough and covered with papillae; the posterior third is smoother, and contains numerous mucous glands and lymph follicles (**lingual tonsil**). The foramen cecum is the remains of the cranial part of the **thyroglossal duct** or diverticulum, from which the thyroid gland develops; the pyramidal lobe of the thyroid gland indicates the position of the lower part of the duct.

## PAPILLAE

The papillae of the tongue (Fig. 16-35) are projections of the corium, thickly distributed over the anterior two-thirds of its dorsum, giving to this surface its characteristic roughness. The varieties of papillae are the **vallate papillae**, **fungiform papillae**, **filiform papillae**, and **papillae simplices**.

**VALLATE PAPILLAE.** The vallate papillae (*circumvallate papillae*) (Fig. 16-35) are large and vary in number from 8 to 12. They are situated on the dorsum of the tongue immediately anterior to the foramen cecum and sulcus terminalis, forming a row on either

side like the limbs of the letter V. Each papilla consists of a projection of mucous membrane 1 to 2 mm wide, attached to the bottom of a circular depression of the mucous membrane, the margin of which is elevated to form a wall (*vallum*); between this and the papilla is a circular sulcus or furrow. The papilla is shaped like a truncated cone, of which the smaller end is attached to the tongue. The broader part of the cone shape is free, projecting a little above the surface of the tongue; it is studded with numerous small secondary papillae and covered by stratified squamous epithelium. The taste buds are especially numerous on the walls of the papilla within the circular furrow.

**FUNGIFORM PAPILLAE.** The fungiform papillae (Fig. 16-36), more numerous than the vallate, are found chiefly at the sides and apex of the tongue but are scattered irregularly and sparingly over the dorsum. They are easily recognized among the other papillae by their large size, round eminences, and deep red color. They are narrow at their attachment to the tongue but broad and round at their free extremities; they are covered with secondary papillae.

**FILIFORM PAPILLAE.** The filiform papillae (*conical papillae*) (Fig. 16-36) cover the anterior two-thirds of the dorsum. They are minute, filiform, and arranged in lines parallel with the two rows of the vallate papillae, except at the apex of the tongue, where their

**FIG. 16-35.** Section of posterior part of dorsum of tongue showing circumvallate papillae and lingual tonsil. (Redrawn from Braus.)

**Fig. 16-36.** Section of anterior part of dorsum of tongue showing fungiform and filiform papillae. (Redrawn from Braus.)

direction is transverse. Projecting from their apices are numerous filamentous processes, or secondary papillae; these have a whitish tint owing to the thickness and density of the epithelium of which they are composed. This epithelium has undergone a peculiar modification: the cells are cornified and elongated into dense, imbricated, brushlike processes. The papillae also contain elastic fibers, which render them firmer and more elastic than the papillae of mucous membrane generally. The larger and longer papillae of this group are sometimes called **conical papillae**.

**PAPILLAE SIMPLICES.** The papillae simplices are similar to those of the skin and cover the entire mucous membrane of the tongue, as well as the larger papillae. They consist of closely set microscopic projections into the layer of epithelium, each containing a capillary loop.

## MUSCLES

The tongue is divided into lateral halves by a median fibrous septum, which extends throughout its entire length and is fixed inferiorly to the hyoid bone. In either half there are two sets of muscles, extrinsic and intrinsic; the former have their origins outside the tongue, the latter are contained entirely within it.

## Extrinsic Muscles

The extrinsic muscles (Fig. 16-37) are:

Genioglossus  
Hyoglossus  
Chondroglossus  
Styloglossus  
Palatoglossus

**GENIOGLOSSUS.** The genioglossus (geniohyoglossus) is a flat, fan-shaped muscle close to and parallel with the median plane. It arises by a short tendon from the superior mental spine on the inner surface of the symphysis menti, immediately above the geniohyoideus muscle. The inferior fibers extend downward, and are attached by a thin aponeurosis to the upper part of the body of the hyoid bone; a few fibers pass between the hyoglossus and chondroglossus to blend with the middle constrictor of the pharynx. The middle fibers pass posteriorly, and the superior ones upward, to enter the whole length of the undersurface of the tongue, from the root to the apex. The muscles of the two sides are separated at their insertions by the median fibrous septum of the tongue; anteriorly, they are more or less blended, the fasciculi decussating in the median plane.

**HYOGLOSSUS.** The hyoglossus arises from the side of the body and from the whole length of the greater horn of the hyoid

**Fig. 16-37.** The extrinsic muscles of the tongue as viewed from the left lateral aspect.

bone, and passes almost vertically upward to enter the side of the tongue, between the styloglossus and the inferior longitudinal muscle. The fibers arising from the body of the hyoid bone overlap those from the greater horn.

**CHONDROGLOSSUS.** The chondroglossus is sometimes described as a part of the hyoglossus, but is separated from it by fibers of the genioglossus, which pass to the side of the pharynx. It is about 2 cm long, and arises from the medial side and base of the lesser horn and contiguous portion of the body of the hyoid bone, and passes directly upward to blend with the intrinsic muscular fibers of the tongue, between the hyoglossus and genioglossus.

A small slip of muscular fibers is occasionally found arising from the cartilago triticea in the lateral thyrohyoid ligament and enter-

ing the tongue with the most posterior fibers of the hyoglossus.

**STYLOGLOSSUS.** The styloglossus, the shortest and smallest of the three styloid muscles, arises from the anterior and lateral surfaces of the styloid process and from the stylo-mandibular ligament. Curving down anteriorly between the internal and external carotid arteries, it divides upon the side of the tongue into two portions: one, longitudinal, enters the side of the tongue near its dorsal surface, blending with the fibers of the inferior longitudinal muscle anterior to the hyoglossus; the other, oblique, overlaps the hyoglossus and decussates with its fibers.

**PALATOGLOSSUS.** The palatoglossus (*glossopalatinus*), although one of the muscles of the tongue, is more closely associated with the soft palate both in situation and

**FIG. 16-38.** Coronal section of tongue, showing intrinsic muscles. (Altered from Krause.)

function; it has consequently been described with the muscles of that structure (page 1441).

### **Intrinsic Muscles**

The intrinsic muscles (Fig. 16-38) are:

Superior longitudinal  
Inferior longitudinal  
Transverse  
Vertical

**SUPERIOR LONGITUDINAL MUSCLE OF THE TONGUE.** The superior longitudinal muscle is a thin stratum of oblique and longitudinal fibers immediately underlying the mucous membrane on the dorsum of the tongue. It arises from the submucous fibrous layer close to the epiglottis and from the median fibrous septum, and runs anteriorly to the edges of the tongue.

**INFERIOR LONGITUDINAL MUSCLE OF THE TONGUE.** The inferior longitudinal muscle is a narrow band situated on the inferior surface of the tongue between the genioglossus and the hyoglossus. It extends from the root to the apex of the tongue; some of its fibers are connected with the body of the hyoid bone, others blend with the fibers of the styloglossus.

**TRANSVERSE MUSCLE.** The transverse muscle consists of fibers that arise from the median fibrous septum and pass lateralward to be inserted into the submucous fibrous tissue at the sides of the tongue.

**VERTICAL MUSCLE.** The vertical muscle is found only at the borders of the anterior part of the tongue; its fibers extend from the upper- to the undersurface.

**NERVES.** The muscles of the tongue are supplied by the hypoglossal nerve.

**ACTIONS.** The movements of the tongue, although numerous and complicated, may be understood by carefully considering the direction of its muscle fibers. The genioglossi, by means of their posterior fibers, draw the root of the tongue anteriorly and protrude the apex from the mouth. The anterior fibers draw the tongue back into the mouth. The two parts acting in their entirety draw the tongue downward, making its superior surface concave from side to side, and forming a channel along which fluids may pass toward the pharynx, as in sucking. The hyoglossi depress the tongue and draw down its sides. The styloglossi draw the tongue upward and backward. The palatoglossi draw the root of the tongue upward.

The intrinsic muscles are mainly concerned with altering the shape of the tongue whereby it becomes shortened, narrowed, or curved in different directions; thus, the superior and inferior longitudinal muscles tend to shorten the tongue, but the former, in addition, turns the tip and sides upward to render the dorsum concave, while the latter pulls the tip downward and renders the dorsum convex. The transverse muscle narrows and elongates the tongue, and the vertical muscle flattens and broadens it. The complex arrangement of the muscular fibers of the tongue and the various directions in which they run give this organ the power to assume the forms necessary for the enunciation of different consonantal sounds.

## STRUCTURE OF THE TONGUE

The tongue is invested by mucous membrane and a submucous fibrous layer.

**MUCOUS MEMBRANE.** The mucous membrane covering the inferior surface of the tongue is thin, smooth, and identical in structure with that lining the rest of the oral cavity. The mucous membrane of the dorsum of the tongue posterior to the foramen cecum and sulcus terminalis is thick and freely movable over the subjacent parts. It contains a large number of lymphoid follicles, which together constitute the **lingual tonsil** (Fig. 16-35). Each follicle forms a round eminence, the center of which is perforated by a minute orifice leading into a funnel-shaped cavity or recess; around this recess are grouped numerous oval or round nodules of lymphoid tissue, each enveloped by a capsule derived from the submucosa, and opening into the bottom of the recesses are the ducts of mucous glands. The mucous membrane on the anterior part of the dorsum of the tongue is thin, intimately adherent to the muscular tissue, and presents numerous minute surface eminences, the **papillae** of the tongue. It consists of a layer of connective tissue, the **corium**, covered with epithelium (Figs. 16-35; 16-36).

The epithelium is stratified squamous, similar to that of the skin, and each papilla has a separate investment from root to summit. The deepest cells may sometimes be detached as a separate layer, corresponding to the rete mucosum, but they never contain pigment.

**CORIUM.** The corium consists of a dense feltwork of fibrous connective tissue, with numerous elastic fibers, firmly connected with the fibrous tissue forming the septa between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels and nerves from which the papillae are supplied, large plexuses of lymphatic vessels, and the glands of the tongue.

**PAPILLAE.** The papillae appear to resemble in structure those of the cutis, consisting of cone-shaped projections of connective tissue, covered with a thick layer of stratified squamous epithelium, and containing one or more capillary loops, among which nerves are distributed in great abundance. If the epithelium is removed, however, one sees that they are not simple elevations like the papillae of the skin, for the surface of each is

studded with minute conical processes that form secondary papillae. In the vallate papillae, the nerves are numerous and large. They are also numerous in the fungiform papillae and end in a plexiform network from which brushlike branches proceed; their mode of termination is similar in the filiform papillae.

**GLANDS OF THE TONGUE.** The tongue has mucous and serous glands.

The **mucous glands** are similar in structure to the labial and buccal glands. They are found especially at the back part behind the vallate papillae, but are also present at the apex and marginal parts. In this connection the anterior lingual glands require special notice. They are situated on the under-surface of the apex of the tongue (Fig. 16-39), one on either side of the frenulum, where they are covered by a fasciculus of muscular fibers derived from the styloglossus and inferior longitudinal muscle. They are 12 to 25 mm long and about 8 mm broad, and each opens by three or four ducts on the under-surface of the apex.

The **serous glands** (v. Ebner's glands<sup>1</sup>) occur only at the back of the tongue in the neighborhood of the taste buds, their ducts opening for the most part into the fossae of the vallate papillae. These glands are racemose, the duct of each branching into several minute ducts, which end in alveoli lined by a single layer of more or less columnar epithelium. Their secretion is watery and probably assists in distributing the substance to be tasted over the taste area.

**SEPTUM.** The septum consists of a vertical layer of fibrous tissue that extends throughout the entire length of the median plane of the tongue, though it does not quite reach the dorsum. It is thicker behind than in front and occasionally contains a small fibrocartilage, about 6 mm long. It is well displayed by making a vertical section across the organ.

**HYOGLOSSAL MEMBRANE.** The hyoglossal membrane is a strong fibrous lamina that connects the undersurface of the root of the tongue to the body of the hyoid bone. This membrane receives some of the fibers of the genioglossi anteriorly.

**TASTE BUDS.** Taste buds, the end-organs of the gustatory sense, are scattered over the mucous membrane of the mouth and tongue

<sup>1</sup>Victor Ebner von Rofenstein (1842-1925): An Austrian histologist (Vienna).

**FIG. 16-39.** The inferior surface of the tongue, with the right side dissected to show the blood vessels, nerve and salivary gland. (Eycleshymer and Jones.)

at irregular intervals. They occur especially in the sides of the vallate papillae. They are described in Chapter 13 under the Organs of the Senses.

**VESSELS AND NERVES.** The main **artery** of the tongue is the lingual branch of the external carotid artery but the facial and ascending pharyngeal arteries also give branches to it. The **veins** open into the internal jugular vein.

The **lymphatics** of the tongue have been described on page 882.

The **sensory nerves** of the tongue are: (1) the lingual branch of the mandibular nerve, which is distributed to the papillae at the anterior part and sides of the tongue, and forms the nerve of ordinary sensibility for its anterior two-thirds; (2) the chorda tympani branch of the facial nerve, which runs in the sheath of the lingual nerve and is generally regarded as the nerve of taste for the anterior two-thirds; this nerve is a continuation of the sensory root of the facial nerve (*nervus intermedius*); (3) the lingual branch of the glossopharyngeal nerve, which is distributed to the mucous membrane at the base and sides of the tongue and to the vallate papillae, and

which supplies both gustatory filaments and fibers of general sensation to this region; (4) the superior laryngeal nerve, which sends some fine branches to the root near the epiglottis.

## Salivary Glands

Three pairs of large salivary glands pour their secretion into the mouth; they are the **parotid**, **submandibular**, and **sublingual** (Fig. 16-40).

### PAROTID GLAND

The parotid gland, the largest of the three, varies in weight from 14 to 28 gm. It lies upon the side of the face, immediately below and in front of the external ear. The main portion of the gland is superficial, somewhat flat and quadrilateral, and is placed between the ramus of the mandible, the mastoid process, and the sternocleidomastoid muscle. Su-

teriorly, it is broad and reaches nearly to the zygomatic arch; inferiorly, it tapers somewhat to about the level of a line joining the tip of the mastoid process to the angle of the mandible. The remainder of the gland is irregularly wedge-shaped, and extends deeply inward toward the pharyngeal wall.

The gland is enclosed within a capsule that is continuous with the deep cervical fascia; the layer covering the superficial surface is dense and closely adherent to the gland. A portion of the fascia that is attached to the styloid process and the angle of the mandible is thickened to form the *stylomandibular ligament*, which intervenes between the parotid and submandibular glands.

**SURFACES.** The **anterior surface** of the

gland is molded on the posterior border of the ramus of the mandible, clothed by the medial pterygoid and masseter muscles. The inner lip of the groove dips, for a short distance, between the two pterygoid muscles, while the outer lip extends for some distance over the superficial surface of the masseter; a small portion of this lip immediately below the zygomatic arch is usually detached, and is named the **accessory part** of the gland.

The **posterior surface** is grooved longitudinally and abuts against the external acoustic meatus, the mastoid process, and the anterior border of the sternocleidomastoid muscle.

The **superficial surface**, slightly lobulated,

**FIG. 16-40.** The salivary glands in a dissection of the right side of the face. (Eycleshymer and Jones.)

is covered by the integument, the superficial fascia containing the facial branches of the great auricular nerve and some small lymph glands, and the connective tissue that forms the capsule of the gland.

The **deep surface** extends inward by means of two processes, one of which lies on the digastric muscle, the styloid process, and the styloid group of muscles, and projects under the mastoid process and the sternocleidomastoid muscle. The other process is situated anterior to the styloid process and sometimes passes into the posterior part of the mandibular fossa behind the temporomandibular joint. The deep surface is in contact with the internal and external carotid arteries, the internal jugular vein, and the vagus and glossopharyngeal nerves.

The gland is separated from the pharyngeal wall by some loose connective tissue.

**STRUCTURES WITHIN THE GLAND.** The external carotid artery lies at first on the deep surface and then in the substance of the gland. The artery gives off its posterior auricular branch, which emerges from the gland posteriorly. It then divides into its terminal branches, the *maxillary* and *superficial temporal*; the former runs anteriorly deep to the neck of the mandible; the latter runs upward across the zygomatic arch and gives off its *transverse facial* branch, which emerges from the anterior part of the gland. Superficial to the arteries are the *superficial temporal* and *maxillary veins*, which unite to form the *retromandibular vein*. A large anastomosing vein emerges from the gland and unites with the facial vein to form the *common facial vein*; the remainder of the vein unites in the gland with the posterior auricular vein to form the *external jugular vein*. On a still more superficial plane is the *facial nerve*, the branches of which emerge from the borders of the gland. Branches of the great auricular nerve pierce the gland to join the facial nerve, while the *auriculotemporal nerve* issues from the upper part of the gland.

**Parotid Duct.** The parotid duct (Stensen's duct<sup>1</sup>) is about 7 cm long. It begins at the anterior part of the gland, crosses the masseter muscle and at the anterior border of this muscle turns medially, nearly at a right angle, where it passes through the corpus

adiposum of the cheek and pierces the buccinator muscle. It runs for a short distance obliquely forward between the buccinator muscle and mucous membrane of the mouth, and then opens upon the oral surface of the cheek by a small orifice opposite the second upper molar tooth. While crossing the masseter muscle, it receives the duct of the accessory gland. In this position it lies between the branches of the facial nerve; the accessory part of the gland and the transverse facial artery are superior to it.

The parotid duct has a wall of considerable thickness; its canal is about 3 to 4 mm in diameter, but at its orifice on the oral surface of the cheek its lumen is greatly reduced in size. It consists of a thick external fibrous coat that contains contractile fibers and an internal or mucous coat lined with low columnar epithelium.

**VESSELS AND NERVES.** The arteries supplying the parotid gland are derived from the external carotid artery and from the branches given off by that vessel in or near its substance. The veins empty themselves in the external jugular vein through some of its tributaries. The lymphatics end in the superficial and deep cervical lymph nodes, passing in their course through two or three nodes placed on the surface and in the substance of the parotid.

The nerves are derived from the plexus of the *sympathetic nerve* on the external carotid artery and from the auriculotemporal nerve. The fibers from the latter nerve are cranial *parasympathetics* derived from the glossopharyngeal and possibly the facial nerve, through the otic ganglion. The sympathetic fibers are regarded as chiefly vasoconstrictors; the parasympathetic fibers, as secretory.

### SUBMANDIBULAR GLAND

The submandibular gland (*glandula mandibularis*; *submaxillary gland*) (Fig. 16-40) is round and about the size of a walnut. Much of it is situated in the submandibular triangle, reaching anteriorly to the anterior belly of the digastric muscle and posteriorly to the stylomandibular ligament, which intervenes between it and the parotid gland. It extends superiorly under the inferior border of the body of the mandible; inferiorly, it usually overlaps the intermediate tendon of the digastric muscle and the insertion of the stylohyoid muscle, and from its deep surface a tongue-like deep process extends anteriorly above the mylohyoid muscle.

<sup>1</sup>Niels Stensen (1638-1686): A Danish physician, anatomist, and physiologist (Copenhagen and Florence).

**SURFACES.** The **superficial surface** of the submandibular gland consists of an upper and a lower part. The *upper part* is directed superficially; it lies partly against the submandibular depression on the inner surface of the body of the mandible and partly on the medial pterygoid muscle. The *lower part* is covered by the skin, superficial fascia, platysma, and deep cervical fascia; it is crossed by the facial vein and by filaments of the facial nerve. In contact with it, near the mandible, are the submandibular lymph nodes.

The **deep surface** is in relation with the mylohyoid, hyoglossus, styloglossus, stylohyoid, and posterior belly of the digastric muscles; in contact with it are the mylohyoid nerve and the mylohyoid and submental vessels. The facial artery is embedded in a groove in the posterior border of the gland.

The **deep process** of the gland extends anteriorly between the mylohyoid laterally and the hyoglossus and styloglossus muscles medially. Above it are the lingual nerve and submandibular ganglion; below it, the hypoglossal nerve and its accompanying vein.

**SUBMANDIBULAR DUCT.** The submandibular duct (Wharton's duct<sup>1</sup>; submaxillary duct) is about 5 cm long and its wall is much thinner than that of the parotid duct. It begins by numerous branches from the deep surface of the gland, and runs anteriorly between the mylohyoid, the hyoglossus, and the genioglossus muscles; then between the sublingual gland and the genioglossus, and opens by a narrow orifice on the summit of a small papilla, the **caruncula sublingualis**, at the side of the frenulum (Fig. 16-39). On the hyoglossus it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it is crossed laterally by the lingual nerve; the terminal branches of the lingual nerve ascend on its medial side.

**VESSELS AND NERVES.** The arteries supplying the submandibular gland are branches of the facial and lingual arteries. Its **veins** follow the course of the arteries. The **secretomotor nerves** are from cranial parasympathetic fibers of the facial nerve, which pass by way of the chorda tympani and submandibular ganglion; the **sympathetic** (*vasomotor*) fibers come from the superior cervical ganglion by way of plexuses on the external carotid and facial arteries.

<sup>1</sup>Thomas Wharton (1616-1673): An English physician and anatomist (London).

## SUBLINGUAL GLAND

The sublingual gland (Fig. 16-40) is the smallest of the three glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the frenulum linguae, in contact with the sublingual depression on the inner surface of the mandible, close to the symphysis. It is narrow, flat, shaped somewhat like an almond, and weighs nearly 2 gm. It is in relation, *superiorly*, with the mucous membrane; *inferiorly*, with the mylohyoid muscle; *posteriorly*, with the deep part of the submandibular gland; *laterally*, with the mandible; and *medially*, with the genioglossus muscle, from which it is separated by the lingual nerve and the submandibular duct.

It has 8 to 20 excretory ducts. One or more join to form the **larger sublingual duct** (duct of Bartholin<sup>2</sup>), which opens into the submandibular duct. Of the **small sublingual ducts** (ducts of Rivinus<sup>3</sup>), some join the submandibular duct; others open separately into the mouth on the elevated crest of mucous membrane (*plica sublingualis*), caused by the projection of the gland, on either side of the frenulum linguae.

**VESSELS AND NERVES.** The sublingual gland is supplied with blood from the sublingual and submental arteries. Its nerves are derived in a manner similar to those of the submandibular gland.

## STRUCTURE OF THE SALIVARY GLANDS

The salivary glands are compound racemose glands consisting of numerous lobes, which are made up of smaller lobules connected by dense areolar tissue, vessels, and ducts. Each lobule consists of the ramifications of a single duct; the branches terminate in dilated ends or alveoli, on which the capillaries are distributed. The alveoli are enclosed by a basement membrane, which is continuous with the membrana propria of the duct and consists of a network of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, which differ in the appearance of

<sup>2</sup>Caspar Thoméson Bartholin, II (1655-1738): A Danish professor of medicine, anatomy, and physics (Copenhagen).

<sup>3</sup>Augustus Quirinus Rivinus (1652-1723): A German anatomist and botanist (Leipzig).

their secreting cells, in their size, and in the nature of their secretion: (1) the mucous variety secretes a viscid fluid that contains mucin; (2) the serous variety secretes a thinner and more watery fluid. The sublingual gland consists of mucous alveoli; the parotid, of serous alveoli. The submandibular contains both mucous and serous alveoli; the latter, however, are preponderant.

The cells in the **mucous alveoli** are cuboidal. In the fresh condition they contain large granules of mucinogen. In hardened preparations, a delicate protoplasmic network is seen, and the cells are clear and transparent. The flat nucleus is usually situated near the basement membrane.

Some alveoli have peculiar crescentic bodies lying between the cells and the membrana propria. They are termed the **crescents of Gianuzzi**,<sup>1</sup> or the **demilunes of Heidenhain**<sup>2</sup> (Fig. 16-41), and are composed of polyhedral granular cells. Fine canaliculi pass between the mucus-secreting cells to reach the demilunes.

In the **serous alveoli**, the cells almost completely fill the cavity, so that the lumen is

<sup>1</sup>Giuseppe Giannuzzi (1839-1876): An Italian physiologist and anatomist (Siena).

<sup>2</sup>Rudolf Peter Heidenhain (1834-1897): A German physiologist (Breslau).

**Fig. 16-41.** Section of the human sublingual gland. b.m., Basement membrane; b.v., blood vessel; c.t., connective tissue stroma; lu., lumen; m.a., mucous alveolus; m.c., mucus-secreting cells; s.a., serous alveolus; s.c., serous crescent (crescent of Gianuzzi or demilune of Heidenhain). 250  $\times$ . (Sobotta.)

hardly perceptible; they contain secretory granules embedded in a closely reticulated protoplasm (Fig. 16-41). The cells are more cubical than those of the mucous type; the nucleus of each is spherical and placed near the center of the cell, and the granules are smaller.

The appearance of both mucous and serous cells varies according to whether the gland is in a resting condition or has recently been active. In the former case the cells are large and contain many secretory granules; in the latter case they are shrunken and contain few granules, which are chiefly collected at the inner ends of the cells.

The **ducts** are lined at their origins by epithelium that differs little from the pavement form. As the ducts enlarge, the epithelial cells change to the columnar type, and the part of the cell next to the basement membrane is finely striated.

The lobules of the salivary glands are richly supplied with blood vessels, which form a dense network in the interalveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue. The nerve fibrils pierce the basement membrane of the alveoli and end in branched varicose filaments between the secreting cells. In the hilum of the submandibular gland is a collection of nerve cells termed **Langley's ganglion**.<sup>3</sup>

### ACCESSORY GLANDS

Besides the salivary glands proper, numerous other glands are found in the mouth. Many of these glands are found at the posterior part of the dorsum of the tongue behind the vallate papillae and also along its margins as far forward as the apex. Others lie around and in the palatine tonsil between its crypts, and large numbers are present in the soft palate, the lips, and the cheeks. These glands have the same structure as the larger salivary glands and are the mucous or mixed type.

### The Fauces

The aperture by which the mouth communicates with the pharynx is called the fauces. The **isthmus faucium** (Fig. 16-42) is bounded,

<sup>3</sup>John Newport Langley (1852-1925): An English physiologist (Cambridge).

**Fig. 16-42.** The mouth cavity. The cheeks have been slit transversely and the tongue pulled forward.

superiorly, by the soft palate; inferiorly, by the dorsum of the tongue; and on either side, by the palatoglossal arch.

#### **PALATOGLOSSAL ARCH**

The palatoglossal arch (*arcus glossopalatinus*; *anterior pillar of fauces*) curves downward from the soft palate near the uvula to the side of the base of the tongue, and is formed by the projection of the palatoglossus muscle with its covering mucous membrane.

#### **PALATOPHARYNGEAL ARCH**

The palatopharyngeal arch (*arcus pharyngopalatinus*; *posterior pillar of fauces*) blends with the free border of the soft palate

near the uvula and curves downward to the side of the pharynx; it is formed by the projection of the palatopharyngeus muscle and covered by mucous membrane. The two arches diverge inferiorly to form a triangular interval, in which the palatine tonsil is lodged.

#### **PALATINE TONSIL**

The palatine tonsil (*tonsil*) (Figs. 16-42; 16-43) is a prominent mass of lymphatic tissue situated at the side of the fauces between the palatoglossal and palatopharyngeal arches. Each tonsil consists of an aggregation of lymphatic nodules underlying the mucous membrane between the arches. The lymphatic tissue does not completely fill the interval between the two arches, however; a small depression, the **supratonsillar fossa**,

**Fig. 16-43.** The nasopharynx and oropharynx in midsagittal section, also showing the entire dorsum of the tongue and the right palatine tonsil. (Redrawn after Sobotta.)

occupies the upper part of the interval. The tonsil extends for a variable distance deep to the palatoglossal arch. The covering fold of mucous membrane reaches across the supra-tonsillar fossa between the two arches; this is sometimes termed the **plica semilunaris**. The remainder of the fold is called the **plica triangularis**. Between the plica triangularis and the surface of the tonsil is a space known as the **tonsillar sinus**, which may be obliterated by its walls becoming adherent. A large portion of the tonsil is below the level of the surrounding mucous membrane, i.e., is embedded, while the remainder projects as the visible tonsil (Fig. 16-43, A). In the child the tonsils are relatively (and frequently absolutely) larger than in the adult, and about one-third of the tonsil is embedded. After puberty, the embedded portion diminishes considerably in size and the tonsil assumes a disc-like form. The shape and size of the tonsil vary considerably in different individuals.

**SURFACES.** The **medial surface** of the tonsil is free except anteriorly, where it is covered by the plica triangularis; it has 12 to 15 orifices (*fossulae tonsillares*) leading into **crypts**

(*cryptae tonsillares*), which may branch and extend deeply into the tonsillar substance.

The **lateral or deep surface** adheres to a fibrous capsule which continues into the plica triangularis. It is separated from the inner surface of the superior pharyngeal constrictor usually by some loose connective tissue; this muscle intervenes between the tonsil and the facial artery with its tonsillar and ascending palatine branches. The internal carotid artery lies posterior and lateral to the tonsil at a distance of 20 to 25 mm.

**WALDEYER'S RING.** The palatine tonsils form part of a circular band of lymphatic tissue (Waldeyer's ring<sup>1</sup>), which guards the opening into the digestive and respiratory tubes (Fig. 16-43). The anterior part of the ring is formed by the submucous lymphatic collections (**lingual tonsil**) on the posterior part of the tongue; the lateral portions consist of the palatine tonsils and tubal tonsils at the openings of the auditory tubes. The ring is completed posteriorly by the pharyngeal tonsil on the posterior wall of the phar-

<sup>1</sup>Heinrich Wilhelm Gottfried Waldeyer (1836-1921): A German professor of pathologic anatomy (Berlin).

ynx. In the intervals between these main masses are smaller collections of lymphoid tissue.

**STRUCTURE OF THE PALATINE TONSIL** (Fig. 16-44). Stratified squamous epithelium, like that of the palate and oral pharynx, covers the free surface of the tonsil and extends down into its substance to form the lining of the crypts. Each **crypt** is surrounded by a layer of lymphatic tissue containing numerous scattered lymphatic nodules, whose germinal centers are especially prominent in children and young adults. A thin connective tissue capsule, derived from the submucosa of the pharynx, encloses the whole tonsil and sends delicate septa between the lymphatic tissue layers surrounding the crypts. The epithelium of the crypts is so invaded by leukocytes in many places that it is scarcely distinguishable from the lymphatic tissue. Polymorphonuclear leukocytes from the blood as well as lymphocytes penetrate the epithelium, and when they are found as free swimming cells in the saliva, they are known as **salivary corpuscles**. Small mucous glands occur in the submucosa about the tonsil but their ducts, as a rule, do not open into the crypts.

**VESSELS AND NERVES.** The arteries supplying the tonsil are the dorsalis linguae from the lingual artery,

the ascending palatine and tonsillar from the facial artery, the ascending pharyngeal from the external carotid artery, the descending palatine branch of the maxillary artery, and a twig from the small meningeal artery.

The **veins**, which form the tonsillar plexus on the lateral side of the tonsil, drain into the pterygoid plexus or the facial vein.

The **lymphatic vessels**, beginning in the dense network of capillaries surrounding the lymphatic tissue, penetrate the pharyngeal wall and pass to the deep cervical nodes. The largest of these nodes, lying beside the posterior belly of the digastric muscle, is especially associated with the tonsil and is easily palpated when the latter is inflamed.

The **nerves** are derived from the middle and posterior palatine branches of the maxillary nerve and from the glossopharyngeal nerve.

**PALATINE APONEUROSIS.** Attached to the posterior border of the hard palate is a thin, firm, fibrous lamella that supports the muscles and gives strength to the soft palate. Laterally it is continuous with the pharyngeal aponeurosis.

#### MUSCLES OF THE PALATE

The muscles of the palate (Fig. 16-45) are:

Levator veli palatini  
Tensor veli palatini

**FIG. 16-44.** Section through one of the crypts of the tonsil. (Stöhr.) Magnified. e, Stratified epithelium of general surface, continued into crypt. f, Nodules of lymphoid tissue—opposite each nodule, numbers of lymph cells are passing into or through the epithelium. s, Cells that have escaped to mix with the saliva as salivary corpuscles.

Musculus uvulae  
Palatoglossus  
Palatopharyngeus

**LEVATOR VELI PALATINI.** The levator veli palatini (*levator palati*) is situated lateral to the choanae and deep to the torus tubarius. It arises from the inferior surface of the apex of the petrous part of the temporal bone and from the medial lamina of the cartilage of the auditory tube. After passing above the superior concave margin of the superior constrictor, it spreads out in the palatine velum, its fibers extending obliquely downward and medialward to the midline, where they blend with those of the opposite side.

**TENSOR VELI PALATINI.** The tensor veli palatini (*tensor palati*) is a thin, ribbon-like

muscle placed lateral and anterior to the levator. It arises by a flat lamella from the scaphoid fossa at the base of the medial pterygoid plate, from the spine of the sphenoid, and from the lateral wall of the cartilage of the auditory tube. Descending vertically between the medial pterygoid plate and the medial pterygoid muscle, it ends in a tendon that winds around the pterygoid hamulus, being retained in this situation by some of the fibers of origin of the medial pterygoid. Between the tendon and the hamulus is a small bursa. The tendon then passes medialward and is inserted into the palatine aponeurosis and into the surface behind the transverse ridge on the horizontal part of the palatine bone.

**MUSCULUS UVULAE.** The musculus uvulae (*azygos uvulae*) arises from the posterior

FIG. 16-45. Dissection of the muscles of the palate, posterior aspect.

nasal spine of the palatine bones and from the palatine aponeurosis. It descends to be inserted into the uvula.

**PALATOGLOSSUS.** The palatoglossus (*glosso-palatinus*) is a small fleshy fasciculus, narrower in the middle than at either end, which forms, with the mucous membrane covering its surface, the palatoglossal arch. It arises from the anterior surface of the soft palate, where it is continuous with the muscle of the opposite side. Passing down anterior to the palatine tonsil, it is inserted into the side of the tongue, some of its fibers spreading over the dorsum and others passing deeply to intermingle with the transverse muscle of the tongue.

**PALATOPHARYNGEUS.** The palatopharyngeus (*pharyngopalatinus*) is a long, fleshy fasciculus narrower in the middle than at either end. With the mucous membrane covering its surface, it forms the palatopharyngeal arch. It is separated from the palatoglossus muscle by a triangular interval, in which the palatine tonsil is lodged. It arises from the soft palate, where it is divided into two fasciculi by the levator veli palatini and the musculus uvulae.

The **posterior fasciculus** lies in contact with the mucous membrane and joins with that of the opposite muscle in the midline; the **anterior fasciculus**, the thicker, lies in the soft palate between the levator and the tensor palatini and joins in the midline the corresponding part of the opposite muscle. Passing down posterior to the palatine tonsil, the palatopharyngeus joins the stylopharyngeus, and is inserted with that muscle into the posterior border of the thyroid cartilage. Some of its fibers are lost on the side of the pharynx and others pass across the midline posteriorly to decussate with the muscle of the opposite side.

**NERVES.** The tensor veli palatini is supplied by a branch of the fifth cranial nerve. The remaining muscles of this group are supplied by the bulbar portion of the accessory nerve through the pharyngeal plexus (pharyngeal branch of the vagus nerve).

**DEGLUTITION.** During the *first stage* of deglutition, the bolus of food is driven back into the fauces by the pressure of the tongue against the hard palate, the base of the tongue being, at the same time, retracted and the larynx raised with the pharynx. During the *second stage*, the entrance to the larynx is closed by drawing the arytenoid cartilages forward toward the cushion of the epiglottis—a movement

produced by the contraction of the thyroarytenoid, the arytenoid, and the aryepiglotticus.

After leaving the tongue, the bolus passes on to the posterior or laryngeal surface of the epiglottis and glides along this for a distance; then the palatoglossi, the constrictors of the fauces, contract behind it. The soft palate is raised slightly by the levator veli palatini and made tense by the tensor veli palatini, and the palatopharyngei, by their contraction, pull the pharynx upward over the bolus and nearly come together; the uvula fills the slight interval between them. By these means the food is prevented from passing into the nasal part of the pharynx. At the same time, the palatopharyngei form an inclined plane directed obliquely downward and backward; along the undersurface of this plane, the bolus descends into the lower part of the pharynx. The salpingopharyngei raise the upper and lateral parts of the pharynx—i.e., those parts above the points where the stylopharyngei are attached to the pharynx.

## STRUCTURE OF THE SOFT PALATE

**MUCOUS MEMBRANE.** The mucous membrane of the soft palate is thin and covered with stratified squamous epithelium on both surfaces, except near the pharyngeal ostium of the auditory tube, where it is columnar and ciliated. The mucous membrane on the nasal surface of the soft palate in the fetus is covered throughout by columnar ciliated epithelium, which subsequently becomes squamous except at its free margin. Beneath the mucous membrane on the oral surface of the soft palate is a considerable amount of lymphoid tissue. The palatine glands form a continuous layer on its posterior surface and around the uvula.

**VESSELS AND NERVES.** The **arteries** supplying the soft palate are the descending palatine branch of the maxillary artery, the ascending palatine branch of the facial artery, and the palatine branch of the ascending pharyngeal artery. The **veins** end chiefly in the pterygoid and tonsillar plexuses. The **lymphatic vessels** pass to the deep cervical nodes.

The **sensory nerves** are derived from the palatine, nasopalatine, and glossopharyngeal nerves.

## The Pharynx

The **pharynx** is that part of the digestive tube placed posterior or dorsal to the nasal cavities, mouth, and larynx. It is a musculo-membranous tube that extends from the inferior surface of the skull to the level of the

cricoid cartilage ventrally and that of the sixth cervical vertebra dorsally.

The cavity of the pharynx (Fig. 16-43) is about 12.5 cm long and is broader in the transverse than in the anteroposterior diameter. Its greatest breadth is immediately below the base of the skull, where it projects on either side, behind the pharyngeal ostium of the auditory tube, as the **pharyngeal recess** (*fossa of Rosenmüller*<sup>1</sup>); its narrowest point is at its termination in the esophagus. It is limited, superiorly, by the body of the sphenoid and basilar part of the occipital bone; inferiorly, it is continuous with the esophagus. Posteriorly, it is separated by a fascial cleft from the cervical portion of the vertebral column, and the prevertebral fascia covering the longus colli and longus capitis muscles. Anteriorly, it is incomplete and is attached in succession to the medial pterygoid plate, pterygomandibular raphe, mandible, tongue, hyoid bone, and thyroid and cricoid cartilages. Laterally, it is connected to the styloid processes and their muscles, and is in contact with the common and internal carotid arteries, the internal jugular veins, the glossopharyngeal, vagus, and hypoglossal nerves, the sympathetic trunks, and small parts of the medial pterygoidei. Seven cavities communicate with it: the two nasal cavities, the two tympanic cavities, the mouth, the larynx, and the esophagus. The cavity of the pharynx may be subdivided into three parts: **nasal**, **oral**, and **laryngeal** (Fig. 16-17).

#### NASAL PART OF PHARYNX

The nasal part of the pharynx (*nasopharynx*) (Fig. 16-46) lies posterior to the nose and above the level of the soft palate: it differs from the oral and laryngeal parts of the pharynx in that its cavity always remains patent. It communicates through the choanae with the nasal cavities anteriorly. On its lateral wall is the **pharyngeal ostium of the auditory tube**, which is bounded posteriorly by the **torus**, a prominence caused by the protrusion of the medial end of the cartilage of the tube under the mucous membrane. A vertical fold of mucous membrane, the **salpingopharyngeal fold**, stretches down

from the torus and contains the salpingopharyngeus muscle. A second and smaller fold, the **salpingopalatine fold**, stretches from the upper part of the torus to the palate. Behind the ostium of the auditory tube is a deep recess, the **pharyngeal recess** (*fossa of Rosenmüller*) (Fig. 16-43).

On the posterior wall is a prominence produced by lymphatic tissue, which is known as the **pharyngeal tonsil**; during childhood this tonsil is likely to be hypertrophied into a considerable mass, at which time it is called **adenoids** (Fig. 16-43). Above the pharyngeal tonsil, in the midline, an irregular flask-shaped depression of the mucous membrane sometimes extends up as far as the basilar process of the occipital bone; this is known as the **pharyngeal bursa**.

#### ORAL PART OF PHARYNX

The oral part of the pharynx reaches from the soft palate to the level of the hyoid bone. It opens into the mouth anteriorly through the isthmus faucium. In its lateral wall, between the two palatine arches, is the **faucial** or **palatine tonsil**.

#### LARYNGEAL PART OF PHARYNX

The laryngeal part of the pharynx reaches from the hyoid bone to the lower border of the cricoid cartilage, where it is continuous with the esophagus. Anteriorly, the entrance of the larynx is formed by the epiglottis; laterally, its boundaries are the aryepiglottic folds. On either side of the laryngeal orifice is a recess, termed the **sinus piriformis**, which is bounded medially by the aryepiglottic fold and laterally by the thyroid cartilage and thyrohyoid membrane.

#### MUSCLES OF THE PHARYNX

The muscles of the pharynx (Fig. 16-47) are:

- Inferior constrictor
- Middle constrictor
- Superior constrictor
- Stylopharyngeus
- Salpingopharyngeus
- Palatopharyngeus

<sup>1</sup>Johann Christian Rosenmüller (1771-1820): A German anatomist and surgeon (Leipzig).

**FIG. 16-46.** The pharynx viewed through a median incision of its posterior wall. (Eycleshymer and Jones.)

**INFERIOR CONSTRICTOR.** The inferior constrictor (Figs. 16-47; 16-48), the thickest of the three constrictors, arises from the sides of the cricoid cartilage in the interval between the cricothyroid muscle anteriorly and the articular facet for the inferior cornu of the thyroid cartilage posteriorly. It arises also from the oblique line on the side of the lamina of the thyroid cartilage, from the surface dorsal to this nearly as far as the posterior border, and from the inferior cornu. From these origins the fibers spread dorsalward and medialward to be inserted with the muscle of the opposite side into the fibrous raphe in the posterior median line of the pharynx. The inferior fibers are horizontal and continuous with the circular fibers of the esophagus; the rest ascend, increasing in obliquity, and overlap the middle constrictor.

**MIDDLE CONSTRICTOR.** The middle constrictor (Figs. 16-47; 16-48) is a fan-shaped

muscle, smaller than the inferior constrictor. It arises from the whole length of the superior border of the greater cornu of the hyoid bone, from the lesser cornu, and from the stylohyoid ligament. The fibers diverge from their origin: the lower ones descend beneath the inferior constrictor, the middle fibers pass transversely, and the upper fibers ascend and overlap the superior constrictor. It is inserted into the posterior median fibrous raphe, blending in the midline with the muscle of the opposite side.

**SUPERIOR CONSTRICTOR.** The superior constrictor (Figs. 16-47; 16-48) is a quadrilateral muscle, thinner and paler than the other two constrictors. It arises from the inferior third of the posterior margin of the medial pterygoid plate and its hamulus, from the pterygomandibular raphe, from the alveolar process of the mandible above the posterior end of the mylohyoid line, and by a few fibers from

FIG. 16-47. The buccinator and muscles of the pharynx.

the side of the tongue. The fibers curve posteriorly to be inserted into the median raphe; they are also prolonged by means of an aponeurosis to the pharyngeal spine on the basilar part of the occipital bone. The superior fibers curve below the levator veli palatini and the auditory tube. The interval between the upper border of the muscle and the base of the skull is closed by the pharyngeal aponeurosis, and is known as the **sinus of Morgagni**.<sup>1</sup>

<sup>1</sup>Giovanni Battista Morgagni (1682-1771): An Italian anatomist and pathologist (Padua).

**STYLOPHARYNGEUS.** The stylopharyngeus (Fig. 16-37), a long, slender muscle, arises from the medial side of the base of the styloid process, passes downward along the side of the pharynx between the superior and middle constrictors, and spreads out beneath the mucous membrane. Some of its fibers are lost in the constrictor muscles while others join with the palatopharyngeus and are inserted into the posterior border of the thyroid cartilage. The glossopharyngeal nerve runs on the lateral side of this muscle and crosses over it to reach the tongue.

**SALPINGOPHARYNGEUS.** The salpingopharyngeus

**Fig. 16-48.** The muscles of the pharynx and the vessels and nerves on its dorsal and lateral aspects; posterior view. (Redrawn after Sobotta.)

ryngeus (Fig. 16-45) arises from the inferior part of the auditory tube near its orifice; it passes downward and blends with the posterior fasciculus of the palatopharyngeus muscle.

**PALATOPHARYNGEUS.** The palatopharyngeus is described with the muscles of the palate.

**NERVES.** The constrictors and the salpingopharyngeus are supplied by branches from the pharyngeal plexus. The inferior constrictor is supplied by additional branches from the external laryngeal and recurrent nerves, and the stylopharyngeus is supplied by the glossopharyngeal nerve.

**ACTIONS.** When deglutition is about to be performed, the pharynx is drawn upward and dilated in different directions to receive the food propelled into it from the mouth. The stylopharyngei, which are much farther removed from one another at their ori-

gin than at their insertion, draw the sides of the pharynx upward and lateralward and so increase its transverse diameter; its breadth in the anteroposterior direction is increased by the larynx and tongue being carried forward in their ascent. As soon as the bolus of food is received in the pharynx, the elevator muscles relax, the pharynx descends, and the constrictors contract upon the bolus and convey it downward into the esophagus.

### STRUCTURE OF THE PHARYNX

The pharynx is composed of three coats: **mucous, fibrous, and muscular.**

The **pharyngeal aponeurosis**, or **fibrous coat**, is situated between the mucous and muscular layers. It is thick superiorly where the muscular fibers are wanting, and is firmly connected to the basilar portion of the occipital and the petrous portions of the

temporal bones. As it descends it diminishes in thickness and gradually blends with the fascia. A strong fibrous band attached to the pharyngeal spine on the inferior surface of the basilar portion of the occipital bone forms the median raphe, which serves as the insertion for all three of the pharyngeal constrictor muscles.

The **mucous coat** is continuous with that lining the nasal cavities, the mouth, the auditory tubes, and the larynx. In the nasal part of the pharynx it is covered by columnar ciliated epithelium; in the oral and laryngeal portions, the epithelium is stratified squamous. Beneath the mucous membrane are found racemose mucous glands; they are especially numerous at the cranial part of the pharynx around the orifices of the auditory tubes.

The **muscular coat** consists of the muscles of the pharynx.

## The Esophagus

The **esophagus** or **gullet** (Fig. 16-49) is a muscular canal, about 23 to 25 cm long, which extends from the pharynx to the stomach. It begins in the neck at the inferior border of the cricoid cartilage, opposite the sixth cervical vertebra, and descends along the ventral aspect of the vertebral column. It passes through the superior and posterior mediastina and the diaphragm, and entering the abdomen, ends at the cardiac orifice of the stomach, opposite the eleventh thoracic vertebra. The general direction of the esophagus is vertical; but it has two slight curves in its course. At its commencement it is placed in the middle line; but it inclines to the left side as far as the root of the neck, gradually passes to the middle line again at the level of the fifth thoracic vertebra, and finally deviates to the left as it passes ventralward to the esophageal hiatus in the diaphragm. The esophagus also has anteroposterior flexures corresponding to the curvatures of the cervical and thoracic portions of the vertebral column. It is the narrowest part of the digestive tube, and is most contracted at its commencement and at the point where it passes through the diaphragm.

**RELATIONS. Cervical Portion.** The cervical portion of the esophagus is in relation, *ventrally*, with the trachea; and at the lower part of the neck,

where it projects to the left side, with the thyroid gland; *dorsally*, it rests upon the vertebral column and longus colli muscles; *on either side* it is in relation with the common carotid artery (especially the left, as it inclines to that side) and parts of the lobes of the thyroid gland. The recurrent nerves ascend between it and the trachea; to its left side is the thoracic duct.

**Thoracic Portion.** The thoracic portion of the esophagus is at first situated in the superior mediastinum between the trachea and the vertebral column, a little to the left of the midline. It then passes dorsal and to the right of the aortic arch and descends in the posterior mediastinum along the right side of the descending aorta. Then it runs ventral and a little to the left of the aorta and enters the abdomen through the diaphragm at the level of the tenth thoracic vertebra. Just before it perforates the diaphragm it has a distinct dilatation. It is in relation, *ventrally*, with the trachea, the left bronchus, the pericardium, and the diaphragm. *Dorsally*, it rests upon the vertebral column, the longus colli muscles, the right aortic intercostal arteries, the thoracic duct, and the hemiazygos veins; near the diaphragm, it rests upon the ventral surface of the aorta. On its *left* side in the superior mediastinum are the terminal part of the aortic arch, the left subclavian artery, the thoracic duct, and left pleura. Running upward in the angle between it and the trachea is the left recurrent nerve; caudally, it is in relation with the descending thoracic aorta. On its *right* side are the right pleura and the azygos vein, which it overlaps. Below the roots of the lungs the vagi descend in close contact with the esophagus; the right nerve passes downward dorsally and the left nerve is ventral to it, the two nerves forming a plexus around the tube.

In the caudal part of the posterior mediastinum, the thoracic duct lies to the right side of the esophagus. More cranially, it is placed dorsal to it, and, crossing about the level of the fourth thoracic vertebra, is continued upward on its left side.

**Abdominal Portion.** The abdominal portion of the esophagus lies in the esophageal groove on the posterior surface of the left lobe of the liver. It measures about 1.25 cm in length, and only its ventral and left aspects are covered by peritoneum. It is somewhat conical, with its base applied to the upper orifice of the stomach, and is known as the **cardiac antrum**.

## STRUCTURE OF THE ESOPHAGUS

The esophagus has four coats: an **external** or **fibrous**, a **muscular**, a **submucous** or **areolar**, and an **internal** or **mucous** coat (Fig. 16-50).

**Fig. 16-49.** Esophagus during the passage of a barium meal. Note that in the upper part of the esophagus, longitudinal folds in the mucous membrane can be identified. The upper arrow points to the shadow of the right bronchus; the lower arrow indicates the tenth thoracic vertebra. Note that the lower part of the esophagus inclines forward away from the vertebral column.

**MUSCULAR COAT.** The muscular coat is composed of two planes of considerable thickness: an external plane of longitudinal and an internal plane of circular fibers.

The *longitudinal fibers* are arranged at the commencement of the tube in three fasciculi: one ventral, which is attached to the vertical ridge on the posterior surface of the lamina of the cricoid cartilage by the *tendo cricoesophageus*; and one at either side, which is continuous with the muscular fibers of the pharynx. As they descend, these fibers blend together to form a uniform layer that covers the outer surface of the tube.

Accessory slips of muscular fibers pass between the esophagus and the left pleura,

where the latter covers the thoracic aorta, the root of the left bronchus, or the back of the pericardium.

The *circular fibers* are continuous above with the inferior constrictor; their direction is transverse at the cranial and caudal parts of the tube, but oblique in the intermediate part.

The muscular fibers in the cranial part of the esophagus are red and consist chiefly of striated muscle; the intermediate part is mixed; and the lower part, with rare exceptions, contains only smooth muscle.

**AREOLAR COAT.** The areolar or submucous coat loosely connects the mucous and muscular coats. It contains blood vessels, nerves,

Fig. 16-50. Cross section through lower part of esophagus of adult cadaver. 5 X.

and mucous glands. The **esophageal glands** are small, compound racemose glands of the mucous type; they are lodged in the submucous tissue, and each opens upon the surface by a long excretory duct.

**MUCOUS COAT.** The mucous coat is thick and reddish cranially and pale caudally. It is disposed in longitudinal folds that disappear on distention of the tube. Its surface is covered throughout with a thick layer of stratified squamous epithelium. Beneath the mucous membrane, between it and the areolar coat, is a layer of longitudinally arranged, nonstriated muscular fibers; this is the **muscularis mucosae**. At the commencement of the esophagus it is absent or is represented by only a few scattered bundles; more caudally it forms a large stratum.

**VESSELS AND NERVES.** The **arteries** supplying the esophagus are derived from the inferior thyroid branch of the thyrocervical trunk, from the descending thoracic aorta, from the bronchial arteries, from the left gastric branch of the celiac artery, and from the left inferior phrenic branch of the abdominal aorta. For the most part they have a longitudinal direction.

The **veins** end in the inferior thyroid, azygos, hemiazygos, and gastric veins, thereby forming an important anastomosis between the portal and systemic venous systems.

The **nerves** are derived from the recurrent vagus, which supplies the striated musculature of the organ, and from the vagus and sympathetic trunks, which supply fibers to the smooth musculature. These cranial parasympathetic and sympathetic fibers form plexuses between the two layers of the muscular coat and in the submucosa, as in the stomach and intestines.

## The Abdomen

The **abdomen** contains the largest cavity in the body. The cranial boundary is formed by the diaphragm, which extends over it as a

dome, so that the cavity extends high into the bony thorax; on the right side it reaches the cranial border of the fifth rib in the mammary line, while on the left side it falls below this level by about 2.5 cm. The caudal boundary is formed principally by the levator ani and coccygeus or diaphragm of the pelvis. To facilitate description, the abdomen is artificially divided into two parts: a cranial and larger part, the *abdomen proper* and a caudal and smaller part, the *pelvis*. The limit between these parts is marked by the superior aperture of the lesser pelvis.

The **abdomen proper** differs from the other great cavities of the body in being bounded for the most part by muscles and fasciae, so that it can vary in capacity and shape according to the condition of the viscera that it contains; in addition, the abdomen varies in form and extent with age and sex. In the adult male, with moderate distention of the viscera, it is oval but flattened dorsoventrally. In the adult female with a fully developed pelvis, it is ovoid, with the narrower pole cranialward; in young children it is also ovoid, but with the narrower pole caudalward.

## BOUNDARIES

The abdomen is bounded *ventrally* and at the sides by the abdominal muscles and the iliacus; *dorsally* by the vertebral column and the psoas and quadratus lumborum muscles; *cranially* by the diaphragm; and *caudally* by the plane of the superior aperture of the lesser pelvis. The muscles forming the boundaries of the cavity are lined upon their inner surfaces by transversalis fascia.

The abdomen contains the greater part of the digestive tube, the liver and pancreas, the spleen, the kidneys, and the suprarenal

glands. Most of these structures, as well as the wall of the cavity in which they are contained, are more or less covered by an extensive and complicated serous membrane, the peritoneum.

## APERTURES

The apertures in the walls of the abdomen for the transmission of structures to or from it are, *cranially*, the **vena caval opening**, the **aortic hiatus**, and the **esophageal hiatus**. *Caudally*, there are two apertures on either side: one for the passage of the femoral vessels and lumboinguinal nerve, and the other for the transmission of the spermatic cord in the male and the round ligament of the uterus in the female. In the fetus, the **umbilicus** transmits the umbilical vessels, the allantois, and the vitelline duct through the ventral wall.

## REGIONS

A simple but effective division of the abdomen commonly used by clinicians is established by two lines intersecting at right angles: the median sagittal line and a transverse line through the umbilicus divide the abdomen into **four quadrants**, an upper and lower right, and an upper and lower left. The more accurate and elaborate division described and depicted in the third chapter (p. 91) is used for reference in many descriptions of abdominal structures.

The following description is based upon the inspection of a cadaver. Always remember that the abdominal organs are highly movable during life, and the arbitrary placement in this account is used to provide a basic knowledge for adaptation to conditions that are seen in patients. Refer frequently to Figures 3-17, 3-19, 3-20, and 3-23 to relate the organs to the skeleton.

## DISPOSITION OF THE ABDOMINAL VISCERA

When the anterior abdominal wall of the cadaver is removed, only a few of the undisturbed organs are plainly visible (Fig. 16-51). *Cranially* and to the right is the **liver**, with the falciform ligament marking its ventral surface into the right and left lobes. The narrow left lobe extends across the median line,

partly concealing the lesser curvature of the stomach. The **stomach** occupies the left cranial region more or less completely, depending on the degree of its distention. The tip of the **gallbladder** may protrude from the caudal border of the right lobe of the liver, and between this and the stomach is the pylorus and the first part of the **duodenum**. Draped caudalward from the greater curvature of the stomach and the first part of the duodenum, a filmy apron, the **greater omentum** (or epiploon), extends caudalward, concealing most of the other intestines. Caudally and on the right, parts of the **descending** and **sigmoid colon** are usually visible and a variable number of coils of the small intestine appear in the caudal part of the cavity. Just above the pubis, the **urinary bladder** is visible if partly distended.

The **large** and **small intestines** are brought into view if the omentum is lifted and turned upward over the stomach and liver (Fig. 16-52). The large intestine forms an arch with the ascending colon on the right, the descending and sigmoid on the left, and the transverse colon, with the omentum attached, forming the top of the arch. The small intestine may be lifted and drawn to the left to display its attachment to the mesentery and the attachment of the colon to the transverse mesocolon. The blind end of the ascending colon, the **cecum**, lies in the hollow of the right ilium, and near the ileocecal junction, the **vermiform appendix** may or may not be visible.

Further inspection requires removal of some of the organs and structures, namely, the small intestine except the duodenum and terminal ileum, the greater omentum, the transverse colon with its mesocolon, and the left lobe of the liver (Fig. 16-53). It is then possible to see the terminal part of the esophagus as it passes through the diaphragm and joins the cardiac end of the stomach. The filmy **lesser omentum** stretches between the lesser curvature of the stomach and the liver and duodenum. The head of the **pancreas** lies in the loop formed by the other three parts of the duodenum. The **spleen** can be brought into view between the greater curvature of the stomach and the diaphragm if the stomach is pulled forcibly toward the liver. Since it is placed rather far dorsally, it may not be seen but it can easily be palpated. If the subject is not obese, a smooth rounded prominence just caudal to the right and left flexures of the

**FIG. 16-51.** Ventral view of the thoracic and abdominal viscera in position after removal of the anterior thoracic and abdominal walls. (Eycleshymer and Jones.)

colon will represent the caudal poles of the two **kidneys**. The sigmoid colon is completely visible and its junction with the rectum may be detected. In the female, if the sigmoid colon is drawn to the left and caudalward, the **uterus** lying in the midline and the uterine tubes on each side may be brought into view. In the midline extending caudally, the prominence caused by the ab-

dominal **aorta** and its bifurcation into the iliac arteries should be discernible.

## The Peritoneum

The **peritoneum** (*tunica serosa*) is the most extensive serous membrane in the body. It consists of a closed sac in the male,

**FIG. 16-52.** Small and large intestines with their mesenteries and blood vessels viewed after the greater omentum has been drawn upward over the chest. (Eycleshymer and Jones.)

part of which is applied against the abdominal parietes, while the remainder is reflected over the contained viscera. In the female the peritoneum is not a closed sac, because the free ends of the uterine tubes open directly into the peritoneal cavity. The part that lines the abdominal wall is named the **parietal peritoneum**; that which is reflected over the contained viscera constitutes the **visceral peritoneum**.

The free surface of the membrane is a smooth layer of flat mesothelium lubricated by a small quantity of serous fluid, which allows the viscera to glide freely against the wall of the cavity or upon each other with the least possible friction. The *attached* surface is connected to the viscera and inner surface of the parietes by means of areolar tissue, which is termed the **subserous fascia**. The parietal portion is separated by a fascial

**Fig. 16-53.** Ventral view of the thoracic and abdominal viscera partially dissected. The anterior pleurae and pericardium have been removed; the structures at the root of the neck, dissected. The left lobe of the liver, the greater omentum, transverse colon, jejunum, and ileum have been removed. (Eycleshymer and Jones.)

cleft from the transversalis fascia that lines the abdomen and pelvis, but it adheres more closely to the undersurface of the diaphragm and in the midline of the anterior wall.

The space between the parietal and visceral layers of the peritoneum is named the **peritoneal cavity**, but under normal conditions this cavity is merely a potential one, since the parietal and visceral layers are in contact. The peritoneal cavity is divided by

a narrow constriction into a greater sac and a lesser sac. The **greater sac**, commonly referred to simply as the peritoneal cavity, is related to the majority of the abdominal structures. The **lesser sac** is named the **omental bursa** and is related only to the dorsal surface of the stomach and closely surrounding structures. The constriction between the two sacs occurs between the liver and the duodenum and is named the **epi-**

**plioic foramen** or *foramen of Winslow*<sup>1</sup> (Figs. 16-53; 16-56).

Certain abdominal viscera are completely surrounded by peritoneum and are suspended from the wall by a thin sheet of peritoneum-covered connective tissue carrying the blood vessels. These sheets are given the general name of mesenteries. Other viscera are more closely attached to the abdominal wall and are only partly covered by peritoneum rather than suspended; these viscera are said to be **retroperitoneal**. No term corresponding to retroperitoneal has been adopted for the suspended viscera; "intra-peritoneal" is unsatisfactory because this would imply that they are inside the peritoneal cavity. The term **mesentery**, when used specifically, refers only to the peritoneal suspension of the small intestine: "entery" refers to the intestine and "mes-" to the peritoneum. Thus, the names of the suspending folds of other organs use only the prefix "meso," for example, the mesocolon, meso-appendix, and mesovarium.

The complicated disposition and variations of the peritoneum in the adult body can be understood only through frequent reference to the changes in position and attachment of the viscera during embryonic and fetal development described in the first part of this chapter.

## PARIETAL PERITONEUM

This discussion of the parietal peritoneum considers the abdominal and pelvic regions, including the omental bursa.

### Abdominal Region

The peritoneum covering the internal surface of the ventral abdominal wall is smooth and relatively uninterrupted by folds and attachments. Certain vestiges of embryonic structures, however, have remained. Between the pubic bone and the umbilicus, a fibrous band in the midline, the middle umbilical ligament, represents the remains of the urachus, and 3 or 4 cm lateral to it are the medial umbilical ligaments, which are fibrous remnants of the obliterated umbilical arteries. The fold of peritoneum over the

urachal remnant is the **middle umbilical fold** (Fig. 16-54); the fold over the arterial remnants is the **medial umbilical fold**. Three or four centimeters lateral to the latter fold is the **lateral umbilical fold**, which is produced by a slight protrusion of the inferior epigastric artery and the interfoveolar ligament. The contracted bladder may have transverse folds extending laterally from its fundus, the **transverse vesical folds**.

Extending cranialward from the umbilicus is the **falciform ligament** of the liver. It is a thin fibrous sheet with a fibrous cord, the **ligamentum teres**, or remnant of the umbilical vein, in its free crescentic border. Its attachment to the wall is narrow from the umbilicus to the cranial surface of the liver, where its two leaves separate and the reflections extend laterally to become the anterior leaf of the **coronary ligament of the liver**.

The **anterior leaf** of the coronary ligament is the anterior boundary of an irregularly oval or triangular area of liver surface, approximately 15 cm in diameter, which has no peritoneal covering and is called the **bare area** of the liver. The posterior boundary of this area is the **posterior leaf** of the coronary ligament, where the peritoneum is reflected from the liver to the diaphragmatic portion of the dorsal abdominal wall. Between the anterior and posterior coronary leaves, the reflection extends laterally into a crescentic fold on each side, forming the **right and left triangular ligaments** of the liver (Fig. 16-55).

On the *left side*, beginning at the falciform and left triangular ligaments on the *anterior abdominal wall*, the peritoneum is uninterrupted by attachments as it passes around the lateral wall and over part of the posterior wall, until it reaches the **gastrophrenic** and **phrenicolienal ligaments**. The latter represent the adult position of the fetal dorsal mesogastrium. The phrenicolienal ligament angles laterally and its more caudal part is reflected from the cranial pole of the left kidney and then meets the splenic or left flexure of the colon. The peritoneum at the reflection of the flexure is prolonged laterally for several centimeters into a narrow fold, the **phrenicocolic ligament**, which represents the left lateral extent of the greater omentum.

The peritoneum of the *anterior and left lateral abdominal wall* from this ligament down to the pelvis and into the rectovesical fossa is uninterrupted by attachments. It is

<sup>1</sup>Jacob Benignus Winslow (1669-1760): A Danish anatomist who worked in Paris.

**Fig. 16-54.** The lower portion of the anterior abdominal wall, viewed from within. The peritoneum has been partially removed from the right side. (Eycleshymer and Jones.)

reflected over the descending colon without mesentery or mesocolon; then the **sigmoid mesocolon** swings laterally into a reflection over the rectum.

The peritoneum of the *right side* of the anterior and lateral abdominal wall extends caudally into the iliac region uninterrupted by attachments. Along the *right side* of the posterior abdominal wall, there is a reflection to the ascending colon and cecum. Between the right triangular ligament and the attachment of the right or hepatic flexure of the colon, an unattached peritoneal surface 3 or 4 cm wide extends medialward and cranialward between the anterior leaf of the coronary ligament of the liver cranially and the **transverse mesocolon** and reflection over the superior part of the duodenum caudally. Medial to the duodenum, the peritoneum of the posterior wall covers the inferior vena cava, and this structure marks the position of the **epiploic foramen**, which

leads toward the left into the **lesser sac** or **omental bursa**.

The reflections of peritoneum from the posterior wall that form the *boundaries of the lesser sac*, beginning at the vena cava, are as follows: the coronary ligament of the liver, along the caudate lobe to the diaphragmatic end of the lesser omentum, the esophagus and the gastrophrenic ligament, the phrenicolienal ligament, containing the tail of the pancreas, the transverse mesocolon, and the first part of the duodenum (Fig. 16-57).

The reflection of peritoneum to the ascending colon extends caudalward along the *right dorsolateral wall* to the cecum in the right iliac fossa. After rounding the blind end of the cecum, the peritoneum from the dorsal wall is reflected to the mesentery of the ileum and the jejunum. The attachment of the mesentery extends medialward as well as cranialward until it reaches the junc-

**Fig. 16-55.** Diagram devised by Delepine to show the lines along which the peritoneum leaves the wall of the abdomen to invest the viscera.

tion of the duodenum with the jejunum at the caudal leaf of the transverse mesocolon. A triangular area of dorsal wall to the right of the mesentery is thus completely surrounded by peritoneal reflections: the ascending colon laterally, the transverse mesocolon cranially, and the mesentery medially. The peritoneum in this triangular area covers part of the right kidney and duodenum.

### Pelvic Region

The peritoneum of the dorsal wall between the mesentery, transverse mesocolon, and descending and sigmoid colons extends into the right side of the pelvis between the rectum and the bladder. Here it follows

closely the surfaces of the pelvic viscera and the inequalities of the pelvic walls, and presents important differences in the two sexes.

**MALE.** In the male (Fig. 16-55), the peritoneum encircles the sigmoid colon, from which it is reflected to the posterior wall of the pelvis as a fold, the **sigmoid mesocolon**. It then leaves the sides and finally the ventral surface of the rectum, and is continued onto the cranial ends of the seminal vesicles and the bladder. On either side of the rectum it forms the **pararectal fossa**, which varies in size with the distention of the rectum. Ventral to the rectum, the peritoneum forms the **rectovesical excavation**, which is limited laterally by peritoneal folds extending from the

sides of the bladder to the rectum and sacrum. Because of their positions, these folds are known as the **rectovesical** or **sacrogenital folds**.

The peritoneum of the ventral pelvic wall covers the superior surface of the bladder and on either side of this viscus forms a depression, termed the **paravesical fossa**, which is limited laterally by the fold of peritoneum covering the ductus deferens. The size of this fossa depends on the state of distention of the bladder; when the bladder is empty, a variable fold of peritoneum, the **plica vesicalis transversa**, divides the fossa into two portions. Between the paravesical and pararectal fossae, the only elevations of the peritoneum are those produced by the ureters and the internal iliac vessels (Fig. 17-15).

**FEMALE.** In the female, pararectal and paravesical fossae similar to those in the male are present: the lateral limit of the paravesical fossa is the peritoneum investing the round ligament of the uterus. The rectovesical excavation, however, is divided by the uterus and vagina into a small anterior vesicouterine excavation and a large, deep, posterior rectouterine excavation. The sacrogenital folds form the margins of the latter, and are continued onto the dorsum of the uterus to form a transverse fold, the **torus uterinus**. The **broad ligaments** extend from the sides of the uterus to the lateral walls of the pelvis; they contain, in their free margins, the uterine tubes, and the ovaries are suspended from their posterior layers. On the lateral pelvic wall dorsal to the attachment of the broad ligament, in the angle between the elevations produced by the diverging internal iliac and external iliac vessels, is the slight **ovarian fossa**, in which the ovary normally lies (Fig. 17-59).

### **Omental Bursa**

The omental bursa or lesser peritoneal sac is so named because a part of its wall is formed by the two omenta (to be described later). On the dorsal abdominal wall, the peritoneum of the greater sac is continuous with that of the lesser sac as it crosses the ventral surface of the inferior vena cava a short distance to the right of the midline (Fig. 16-57). This passage of continuity between the two sacs is the **epiploic foramen** or **foramen of Winslow**.

**EPIPLOIC FORAMEN.** The epiploic foramen (Fig. 16-56) is a peritoneal-covered passage that usually admits two fingers. It can easily be located with a probing finger in the abdominal cavity by pushing a way between the inferior vena cava and the free edge of the hepatoduodenal ligament in the region between the neck of the gallbladder and the first part of the duodenum (Fig. 16-56). The epiploic foramen is bounded *ventrally* by the free border of the lesser omentum, with the common bile duct, the hepatic artery, and the portal vein between its two layers; *dorsally* by the peritoneum covering the inferior vena cava; *cranially* by the peritoneum on the caudate process of the liver; and *caudally* by the peritoneum covering the commencement of the duodenum and the hepatic artery before it passes between the two layers of the lesser omentum.

**BOUNDARIES OF OMENTAL BURSA.** The boundaries of the omental bursa will now be evident. It is bounded *ventrally* by the caudate lobe of the liver, the lesser omentum, the stomach, and the greater omentum. *Dorsally*, it is limited by the greater omentum, the transverse colon, the transverse mesocolon, the ventral surface of the pancreas, the left suprarenal gland, and the cranial end of the left kidney. To the right of the esophageal opening of the stomach it is formed by the part of the diaphragm that supports the caudate lobe of the liver. *Laterally*, the bursa extends from the epiploic foramen to the hilum of the spleen, where it is limited by the phrenicolienal and gastrolienal ligaments.

The omental bursa, therefore, consists of a series of pouches or **recesses** to which the following terms are applied: (1) the **vestibule**, a narrow channel that continues from the epiploic foramen over the head of the pancreas to the gastropancreatic fold; this fold extends from the omental tuberosity of the pancreas to the right side of the fundus of the stomach and contains the left gastric artery and the coronary vein; (2) the **superior omental recess**, which is found between the caudate lobe of the liver and the diaphragm; (3) the **lienal recess**, located between the spleen and the stomach; (4) the **inferior omental recess**, which comprises the remainder of the bursa (Fig. 16-57).

In the fetus the bursa reaches as low as the free margin of the greater omentum, but in the adult its vertical extent is usually more

**FIG. 16-56.** The epiploic foramen (of Winslow) and neighboring structures. (Eycleshymer and Jones.)

limited owing to adhesions between the layers of the omentum. During a considerable part of fetal life the transverse colon is suspended from the posterior abdominal wall by a mesentery of its own, the greater omentum passing ventral to the colon (Fig. 16-13). This condition occasionally persists throughout life, but as a rule adhesion occurs between the mesentery of the transverse colon and the posterior layer of the greater omentum, so that the colon appears to receive its peritoneal covering by the splitting of the two posterior layers of the latter fold (Fig. 16-14). In the adult the omental bursa inter-

venes between the stomach and the structures on which the viscus lies, and therefore performs the functions of a serous bursa for the stomach.

### VISCERAL PERITONEUM

The visceral peritoneum covers all or part of each abdominal organ and forms the various mesenteries, omenta, and ligaments associated with them. Numerous peritoneal folds extend between the various organs or connect them to the parietes; they serve to

**Fig. 16-57.** View of the posterior wall of the lesser sac of the peritoneum (omental bursa), showing the attachment of the ligaments of the liver, the hepatoduodenal ligament, the root of the mesentery and transverse mesocolon, and reflection of peritoneum from the stomach. The aorta, pancreas, kidneys, spleen, and duodenum are covered by peritoneum. (Töndury, *Angewandte und topographische Anatomie*, courtesy of Georg Thieme Verlag.)

hold the viscera in position and at the same time enclose the vessels and nerves proceeding to them.

### Mesenteries

The mesenteries are: the mesentery proper, the transverse mesocolon, and the sigmoid mesocolon. In addition, an ascending and a descending mesocolon are sometimes present.

**MESENTERY PROPER.** The mesentery proper is the broad, fan-shaped fold of peritoneum that connects the convolutions of the jejunum and ileum with the dorsal wall of the abdomen. Its root—the part connected with the structures ventral to the vertebral column—is about 15 cm long, extending obliquely from the duodenojejunal flexure at the left side of the second lumbar vertebra to the right sacroiliac articulation (Fig. 16-55). Its intestinal border is about 6 meters long, and here the two layers separate to enclose the intestine and form its peritoneal coat. The cranial end is narrow but widens rapidly to about 20 cm, and it is thrown into numerous plaits or folds. This part of the mesentery suspends the small intestine and contains between its layers the intestinal branches of the superior mesenteric artery, with the accompanying tributaries of the portal vein, the plexuses of nerves, the lacteal vessels, and the mesenteric lymph nodes.

**TRANSVERSE MESOCOLON.** The transverse mesocolon is a broad fold that connects the transverse colon to the dorsal wall of the abdomen. It is continuous with the greater omentum along the ventral surface of the transverse colon. Its two peritoneal layers diverge along the anterior border of the pancreas. It contains between its layers the vessels that supply the transverse colon.

**SIGMOID MESOCOLON.** The sigmoid mesocolon is the fold of peritoneum that retains the sigmoid colon in connection with the pelvic wall. Its line of attachment forms a U-shaped curve, with the apex of the curve placed about the point of division of the left common iliac artery. It is continuous with the **iliac mesocolon** on the left and ends in the median plane at the level of the third sacral vertebra over the rectum. The sigmoid and superior rectal vessels run between the two layers of this fold.

**OTHER FEATURES.** In most cases the peritoneum covers only the ventral surface and

sides of the ascending and descending parts of the colon. Sometimes, however, these parts of the colon are surrounded by the serous membrane and are attached to the posterior abdominal wall by an ascending and a descending mesocolon respectively. A fold of peritoneum, the **phrenicocolic ligament**, is continued from the left colic flexure to the diaphragm opposite the tenth and eleventh ribs; it forms a pocket that supports the spleen and therefore has received the name, **sustentaculum lienis**.

The **appendices epiploicae** are small pouches of peritoneum that are filled with fat and situated along the colon and upper part of the rectum. They are appended chiefly to the transverse and sigmoid parts of the colon.

### Omenta

There are two omenta, the lesser and the greater.

**LESSER OMENTUM.** The lesser omentum (*omentum minus*; *small omentum*; *gastrohepatic omentum*) extends to the liver from the lesser curvature of the stomach and the commencement of the duodenum. It is continuous with the two layers of peritoneum that cover respectively the ventral and dorsal surfaces of the stomach and the first part of the duodenum. The two peritoneal layers leave the stomach and duodenum as a thin membrane and ascend to the porta of the liver. To the left of the porta, the omentum is attached to the bottom of the fossa for the ductus venosus, along which it extends to the diaphragm, where the two layers separate to embrace the end of the esophagus. At the right, the omentum ends in a free margin, which constitutes the ventral boundary of the epiploic foramen. The portion of the lesser omentum located between the liver and stomach is termed the **hepatogastric ligament**; that between the liver and duodenum is the **hepatoduodenal ligament** (Fig. 16-56). Between the two layers of the hepatoduodenal ligament, close to the right free margin, are the hepatic artery, the common bile duct, the portal vein, lymphatics, and the hepatic plexus of nerves; all of these structures are enclosed in a fibrous capsule (**Glisson's capsule**<sup>1</sup>). The right and left gastric vessels run

<sup>1</sup>Francis Glisson (1597-1677): An English physician and anatomist (Cambridge).

between the layers of the lesser omentum, where they are attached to the stomach.

**GREATER OMENTUM.** The greater omentum (*omentum majus*; *gastrocolic omentum*) (Fig. 16-51) is a filmy apron draped over the transverse colon and coils of the small intestine. It is attached along the greater curvature of the stomach and the first part of the duodenum; its left border is continuous with the gastrosplenic ligament. If it is lifted and turned back cranialward over the stomach and liver, one sees that it adheres to the transverse colon along the latter's whole length across the abdomen (Fig. 16-52). The greater omentum may be composed of a single membrane covered with peritoneum on both surfaces from the colon to its free caudal border, but in some people a variable amount of omentum near the colon is often composed of two peritoneum-covered membranes with a pocket between them. If the greater omentum contains this pocket, only the dorsal of the two membranes is attached to the colon, and the pocket opens into the omental bursa. This is best understood by referring to the conditions in the fetus depicted in the diagrams of Figure 16-14.

The membrane forming the greater omentum is thin, transparent, and fenestrated, except where there are blood vessels and accumulations of fat. The membrane between the stomach and the colon is the **gastrocolic ligament**. The right and left gastropiploic blood vessels run between the two peritoneal layers of this ligament near their attachment to the greater curvature of the stomach, and they must be avoided when the ligament is cut to gain access to the omental bursa.

The greater omentum is a remarkable structure. It is greatly movable in the living individual and seems to have the ability to spread itself in areas where its presence is useful for the bodily economy. For example, in a patient with a ruptured appendix, the omentum may be found covering the area, walling off the infection to form an abscess and preventing generalized peritonitis. Occasionally the omentum finds its way into the sac of a hernia, where it may form adhesions, close up the sac, and produce a "spontaneous repair" of the hernia. In a cadaver it may be free and spread over the intestines or bunched up near the colon or in a recess. Adhesions, except along the stomach and colon, are abnormal and the result of inflammatory processes.

## Ligaments

The term "ligament" has two meanings. When applied to structures related to a joint, it is a strong fibrous cord or sheet. When applied to the peritoneum it is merely a layer of serous membrane and has little or no tensile strength. The **ligaments of the peritoneum** are the parts of the membrane that extend between two structures and usually derive their names from these two structures—the gastrosplenic ligament, for example. The ligaments are described in detail along with the organs to which they are related.

## PERITONEAL RECESSES OR FOSSAE

In certain parts of the abdominal cavity, recesses of peritoneum form cul-de-sacs or pouches (**retroperitoneal fossae**), which have surgical importance in connection with the possible occurrence of *intraabdominal* or *retroperitoneal hernias* (Mayo et al., 1941). The largest of these is the omental bursa (already described), but several other smaller fossae require mention. These may be divided into three groups: duodenal, cecal, and intersigmoidal fossae.

### Duodenal Fossae

Three appear fairly constantly (Figs. 16-58; 16-59): the inferior duodenal fossa, the superior duodenal fossa, and the duodenojejunal fossa. Two appear occasionally or rarely: the paraduodenal fossa and the retroduodenal fossa.

**INFERIOR DUODENAL FOSSA.** The inferior duodenal fossa, present in about 75% of bodies, is situated opposite the third lumbar vertebra on the left side of the ascending portion of the duodenum. It is bounded by a thin sharp fold of peritoneum, and if the tip of the index finger is introduced into the fossa, it passes a little distance caudalward behind the ascending portion of the duodenum.

**SUPERIOR DUODENAL FOSSA.** The superior duodenal fossa, present in about 50% of bodies, often coexists with the inferior fossa. It lies on the left of the ascending portions of the duodenum, at the level of the second lumbar vertebra. It extends cranialward behind the sickle-shaped duodenojejunal fold, and has a depth of about 2 cm.

**DUODENOJEJUNAL FOSSA.** The duodenojejunal fossa exists in about 20% of bodies. It

FIG. 16-58. Superior and inferior duodenal fossae. (Poirier and Charpy.)

lies between the right and left duodenumesocolic folds, extending cranialward behind the duodenojejunal junction toward the pancreas between the aorta on the right and the kidney on the left. It has a depth of 2 to 3 cm; its orifice is nearly circular and will admit the tip of the finger.

**PARADUODENAL FOSSA.** The paraduodenal fossa, rarely found, lies a short distance to the left of the ascending portion of the duodenum behind a peritoneal fold that contains the inferior mesenteric vein. The presence of a large fossa, containing most of the small intestine, has been explained as an abnormal rotation of the gut in embryonic

development (Mayo et al., 1941). A similar condition is usual in squirrel monkeys.

**RETRODUODENAL FOSSA.** The retroduodenal fossa, only occasionally present, lies dorsal to the horizontal and ascending parts of the duodenum and ventral to the aorta.

#### Cecal Fossae

The cecal fossae (*pericecal folds*) are three principal pouches or recesses in the neighborhood of the cecum (Figs. 16-60 to 16-62):

Superior ileocecal fossa  
Inferior ileocecal fossa  
Cecal fossa

FIG. 16-59. Duodenojejunal fossa. (Poirier and Charpy.)

**Fig. 16-60.** Superior ileocecal fossa. (Poirier and Charpy.)

**SUPERIOR ILEOCECAL FOSSA.** The superior ileocecal fossa is formed by a fold of peritoneum that arches over the branch of the ileocolic artery that supplies the ileocolic junction. The fossa is a narrow chink situated between the mesentery of the small intestine, the ileum, and the small portion of the cecum behind.

**INFERIOR ILEOCECAL FOSSA.** The inferior ileocecal fossa is situated behind the angle of junction of the ileum and the cecum. It is formed by the ileocecal fold of peritoneum (*bloodless fold of Treves*<sup>1</sup>), the upper border of which is fixed to the ileum opposite its mesenteric attachment, while the lower bor-

<sup>1</sup>Frederick Treves (1853–1923): An English surgeon (London).

der, passing over the ileocecal junction, joins the mesenteriole of the vermiform appendix and sometimes the appendix itself. Between this fold and the mesenteriole of the appendix is the inferior ileocecal fossa. It is bounded cranially by the dorsal surface of the ileum and the mesentery; ventrally and caudally by the ileocecal fold, and dorsally by the upper part of the mesenteriole of the vermiform appendix.

**CECAL FOSSA.** The cecal fossa is situated immediately behind the cecum, which has to be raised to bring it into view. It varies much in size and extent. In some cases it is sufficiently large to admit the index finger, and extends upward behind the ascending colon in the direction of the kidney; in others it is merely a shallow depression. It is bounded on the right by the **cecal fold**, which is attached by one edge to the abdominal wall from the caudal border of the kidney to the iliac fossa, and by the other edge to the posterolateral aspect of the colon. In some instances additional fossae, the **retrocecal fossae**, are present.

### *Intersigmoid Fossa*

The intersigmoid fossa (*recessus intersigmoideus*) (Fig. 16-84) is constant in the fetus and during infancy, but disappears in a certain percentage of individuals as age advances. When the sigmoid colon is drawn cranialward, the left surface of the sigmoid mesocolon is exposed, and on it will be seen a funnel-shaped recess of the peritoneum lying on the external iliac vessels in the interspace between the psoas and iliacus muscles. This is the intersigmoid fossa, which

**Fig. 16-61.** Inferior ileocecal fossa. The cecum and ascending colon have been drawn lateralward and downward, the ileum upward and backward, and the vermiform appendix downward. (Poirier and Charpy.)

**Fig. 16-62.** The cecal fossa. The ileum and cecum are drawn dorsalward and cranialward. (Souligoux.)

lies dorsal to the sigmoid mesocolon and ventral to the parietal peritoneum. The fossa varies in size; in some instances it is a mere dimple, whereas in others it will admit the whole of the index finger.

## The Stomach

The **stomach** (*ventriculus*; *gaster*) is situated in the right upper quadrant of the abdomen, partly covered by the ribs. It lies in a recess in the epigastric and left hypochondriac regions bounded by the anterior abdominal wall and the diaphragm, between the liver and the spleen.

### SHAPE AND POSITION

The shape and position of the stomach are so greatly modified by changes within itself and in the surrounding viscera that no single form can be described as typical. The chief modifications are determined by (1) the amount of the stomach contents, (2) the stage that the digestive process has reached, (3) the degree of development of the gastric musculature, and (4) the condition of the adjacent intestines. It is possible, however, by comparing a series of stomachs, to de-

termine certain points more or less common to all (Figs. 16-63; 16-64).

According to Moody (1926), radiographs of the normal erect living body show the ordinary range of variation of the most caudal part of the greater curvature to be 7.3 cm above to 13.5 cm below the interiliac line in males and 6.5 cm above to 13.7 cm below the line in females. It is below the interiliac line in 74.4% of males and 87% of females. With the body horizontal, the most caudal part of the greater curvature in males is 16.5 cm above to 7.3 cm below the interiliac line, and in females, 15.5 cm above to 8.4 cm below the line. The most common position in the erect male (26%) is 2.6 to 5 cm below the interiliac line, and in the horizontal male (22.4%), 2.5 to 5 cm above the interiliac line. The most common position in the erect female (22.4%) is 5 to 7.5 cm below the interiliac line and in the horizontal female (24%), 2.5 to 5 cm above the interiliac line (Fig. 16-63).

The position of the pylorus in the erect living body of the male varies from 14.5 cm above to 8 cm below the iliac line, and in the female, 15 cm above to 2.5 cm below the interiliac line. The range of position of the pylorus in regard to the sagittal axis of the erect body varies in males from 8.8 cm to the right to 2 cm to the left of the axis. In 84% it is to the right of the axis. In females the posi-

**FIG. 16-63.** Average position of the stomach based on x-ray studies. Standing position in black; reclining position in red. (Eycleshymer and Jones.)

tion ranges from 6 cm to the right to 2.6 cm to the left of the sagittal axis. In 18.5% it is to the right. The most common position in both males and females is 2.5 to 5 cm to the right.

### OPENINGS

The opening from the esophagus into the stomach is known as the **cardiac orifice**, so named because of its close relationship with the part of the diaphragm upon which the heart rests. The short abdominal portion of the esophagus is situated to the left of the midline at the level of the tenth thoracic vertebra. It curves sharply to the left and dilates into the **cardiac antrum**. The right margin of the esophagus is continuous with the lesser curvature of the stomach; the left margin joins the greater curvature at an acute angle, forming the **incisura cardiaca** (cardiac notch).

The opening of the stomach into the duodenum is the **pyloric orifice**, which lies to the right of the midline at the level of the cranial border of the first lumbar vertebra. Its position is usually indicated on the surface of the stomach by a circular groove, the duodenopyloric constriction.

### CURVATURES

The **lesser curvature** (Fig. 16-67) forms the right or concave border of the stomach. Nearer to its pyloric than its cardiac end is a well-marked notch, the **angular incisure** (Fig. 16-64), which varies somewhat in position with the state of distention; it serves to separate the stomach into a right and a left portion. The hepatogastric ligament (*lesser omentum*), which contains the left gastric artery and the right gastric branch of the

**FIG. 16-64.** Diagram showing the subdivisions of the human stomach. (F. T. Lewis.)

hepatic artery, is attached to the lesser curvature.

The **greater curvature**, directed to the left and ventralward, is four or five times as long as the lesser curvature. Starting from the cardiac orifice at the incisura cardiaca, it arches cranialward and to the left; the highest point of the convexity is level with the sixth left costal cartilage. From this level it curves more gradually caudalward, with a slight convexity to the left as low as the cartilage of the ninth rib; it then continues to the right, to end at the pylorus. Directly opposite the angular incisure of the lesser curvature, the greater curvature presents a dilatation, which is the **pyloric antrum**. This dilatation is limited on the right by a slight groove, the **sulcus intermedius**, which is about 2.5 cm from the pyloric ostium. The portion between the sulcus intermedius and the pyloric ostium is termed the **pyloric canal**. Attached along the greater curvature are certain mesenteric membranes derived from the embryonic dorsal mesogastrium. From the fundus, the gastrophrenic ligament extends to the diaphragm, and from the cranial part of the body, the gastrolial ligament runs to the spleen. The greater omentum is suspended from the remainder of the curvature.

## SURFACES

When the stomach is contracted, the two surfaces between the curvatures face somewhat cranialward and caudalward, but when it is partly distended, they face ventralward and dorsalward (Fig. 16-53).

**VENTRAL SURFACE.** The ventral surface (anterosuperior surface) (Fig. 16-53) is covered with peritoneum of the greater omentum. At the left and cranially it is against the diaphragm, which separates it from the base of the left lung, the heart, and the seventh, eighth, and ninth ribs and the corresponding intercostal spaces. The right portion is in relation with the left and quadrate lobes of the liver and the anterior abdominal wall. When the stomach is empty, the transverse colon may lie on the caudal part of this surface.

**DORSAL SURFACE.** The dorsal surface (posteroinferior surface) (Fig. 16-57) is covered with peritoneum of the lesser sac or omental bursa. It is in relation with the diaphragm, the spleen, the left suprarenal

gland, the cranial part of the left kidney, the ventral surface of the pancreas, the left colic flexure, and the transverse mesocolon. These structures form a shallow **stomach bed** in which the organ rests (Fig. 16-57). The transverse mesocolon separates the stomach from the duodenojejunal junction and the rest of the small intestine. When the stomach is distended, especially if the patient is in the upright posture, the pyloric half of the stomach slides caudalward over the mesocolon and colon and may reach into the pelvis (Figs. 16-65; 16-66).

## COMPONENT PARTS

A plane passing through the angular incisure on the lesser curvature divides the stomach into a left portion or **body** and a right or **pyloric portion** (Fig. 16-64). The cranial portion of the body is the **fundus**, which is marked off from the remainder of the body by a plane passing horizontally through the cardiac orifice. To the right of a plane through the sulcus intermedius at right angles to the long axis of this portion is the pyloric canal (Fig. 16-64), which ends in the thickened muscular ring, the **pyloric sphincter**.

A stomach examined during the process of digestion will be divided by a muscular constriction into a large, dilated left portion and a narrow, contracted, tubular right portion. The constriction appears in the body of the stomach and does not follow any of the anatomic landmarks; indeed, it shifts gradually toward the left as digestion progresses, i.e., more of the body is gradually absorbed into the tubular part.

## INTERIOR OF THE STOMACH

When examined after death, the stomach is usually fixed at some stage of the digestive process. A common form is that shown in Figure 16-67. If the viscus were laid open by a section through the plane of its two curvatures, it would consist of two segments: a large globular portion on the left and a narrow tubular part on the right. These correspond to the clinical subdivisions of fundus and pyloric portions already described, and are separated by a constriction that indents the body and the greater curvature but does

**Fig. 16-65.** Normal stomach after a barium meal. The tone of the muscular wall is good and supports the weight of the column in the body of the organ. The arrow points to the duodenal cap, below which a gap in the barium indicates the position of the pylorus.

not involve the lesser curvature. To the left of the cardiac orifice is the incisura cardiaca: the projection of this notch into the cavity of the stomach increases as the organ distends, and it supposedly acts as a valve preventing regurgitation into the esophagus. In the pyloric portion are seen the elevation corresponding to the angular incisure and the circular projection from the duodenopyloric constriction, which forms the pyloric valve; the separation of the pyloric canal from the rest of the pyloric part is scarcely indicated.

### STRUCTURE OF THE STOMACH

The wall of the stomach has four coats: **mucous, submucous, muscular, and serous.**

**MUCOUS MEMBRANE.** The mucous membrane (Fig. 16-68) that lines the stomach has a soft, velvety appearance and pinkish color in the fresh state. It is thrown into thick folds, known as **rugae**, which tend to have a longitudinal direction along the lesser cur-

vature and at the pylorus, but elsewhere resemble a honeycomb. The folds involve both the mucosa and the submucosa, but they are transient and movable, and are gradually obliterated as the stomach distends.

The surface of the membrane does not appear smooth when examined with a lens, because closely scattered everywhere are the openings of the **gastric pits** or **foveolae**. On the cut surface of the stomach wall, the mucous membrane appears quite thick (5 mm) because tubular gastric glands extend down into it from the foveolae (Fig. 16-69).

The **lining epithelium** that covers the surface and extends down into the foveolae is composed of tall columnar cells of characteristic and rather uniform appearance; these are called **theca cells**. They secrete mucus, and within the part of the cell toward the surface, the precursor of the mucus can be seen in a shallow pocket or **theca**, much smaller and more difficult to identify

**Fig. 16-66.** Atonic stomach after a barium meal. This stomach contains the same amount of barium as the stomach in Fig. 16-65. Arrow 1 points to the shadow of the right breast; arrow 2, to the pylorus; arrow 3, to the upper part of the body of the stomach, where longitudinal folds can be seen in the mucous membrane. X X marks a wave of peristalsis.

Interior of the stomach.

FIG. 16-67.

than the pocket of a goblet cell. They do not have a cuticular border like that seen in the cells of the intestine, and there are no goblet cells.

**Gastric Glands.** The gastric glands are simple tubular glands that open in groups of two or three into the bottoms of the gastric pits. Three kinds may be distinguished: (a) fundic glands, (b) cardiac glands, and (c) pyloric glands (the last two, being local modifications, will be described with the appropriate parts). Frequently, the **fundic glands** are simply called gastric glands, because they

are the most characteristic glands of the stomach and they occur throughout the fundus and body. The epithelial cells are of two types: chief cells and parietal cells.

**Chief Cells.** The **chief cells** are again subdivided into neck chief cells and body chief cells. The **neck chief cells** provide a transition between the lining epithelium of the foveolae and the secreting part of the glands. They are cuboidal or columnar, have a basophilic cytoplasm and, since they appear to be the source of new epithelial cells, they frequently contain mitotic nuclei. The **body**

Section through wall of stomach of adult cadaver. 5 ×.

FIG. 16-68.

**Fig. 16-69.** Section through the body of the stomach of a 22-year-old man. f, Gastric fovea; g.g., gastric gland; m.m., muscularis mucosae. 50  $\times$ . (Sobotta.)

**chief cells** extend down to the bottom of the glands. They resemble the neck chief cells but they are slightly more basophilic and have a prominent basal striation. They contain many small secretion granules, which can be made clearly visible with special stains; these cells secrete pepsin.

**Parietal Cells.** The parietal cells are the most characteristic cells in the gastric glands. Their name originated from the fact that they are pushed back against the basement membrane. They do not form a continuous layer, but are scattered all along the walls of the glands, separated by several chief cells and usually overlapped by parts of the neighboring body chief cells, which intervene between them and the internal surface of the gland. They are four or five times as large as chief cells, have a granular, intensely acidophilic cytoplasm, and are the source of the hydrochloric acid in the gastric juice (Fig. 16-70). The tissue surrounding and intervening between the gastric pits and the glands is composed of areolar connective tissue, blood and lymphatic capillaries with scattered lymphocytes, and occasionally even lymphatic nodules. The boundary between the mucosa and the submucosa is marked by a thin sheet of smooth muscle cells, the **muscularis mucosae**, which is composed of an inner circular and outer longitudinal layer.

**SUBMUCOUS COAT.** The submucous coat is composed of areolar connective tissue and blood and lymphatic vessels. It extends up into the rugae.

**MUSCULAR COAT.** In addition to the two layers of smooth muscle fibers characteristic of the digestive tube—inner circular and outer longitudinal—the muscular coat of the stomach has a layer of oblique fibers. The inner circular layer is well represented over the entire organ (Fig. 16-68). The outer longitudinal layer is not as uniform as the circular layer and is more concentrated along the lesser curvature and the greater curvature (Fig. 16-71). The oblique fibers are internal to the circular fibers, occur chiefly at the cardiac end of the stomach, and spread over the ventral and dorsal surfaces (Figs. 16-71; 16-72).

**SEROUS COAT.** The serous coat is composed of a small amount of areolar tissue that connects the mesothelial layer of the peritoneum to the muscular coat. It contains some of the larger blood vessels and lymphatics. A narrow strip along the lesser and greater curvatures, where the two omenta are attached, is not covered by peritoneum.

### *Cardiac Region*

The cardiac portion of the stomach has certain peculiarities. The stratified squamous epithelium of the esophagus is ab-

**Fig. 16-70.** Higher magnification of transition from fovea to gastric gland shown in Figure 16-69. c.c., Chief cell; l.f., lumen of fovea; l.g., lumen of gland; p.c., parietal cell. 5000  $\times$ . (Sobotta.)

ruptly replaced by the columnar epithelium of the stomach. The **cardiac glands** are longer, more twisted, and contain no parietal cells; they resemble the esophageal glands and secrete mucus. Aggregations of lymph nodes or lymphatic nodules are common. The muscular layers are continuous with those of the esophagus.

### **Pylorus**

The pylorus is distinctively marked by the thickening of the circular layer into the **pyloric sphincter**, which acts as a valve to close the lumen. The lining epithelium makes an abrupt transition from the gastric type with its theca cells to the intestinal epithelium type with striated cuticular border and interspaced goblet cells. The **pyloric glands** are devoid of parietal cells; they are longer

and more tortuous than the gastric glands and have the appearance of mucus-secreting cells. At the transition from stomach to duodenum, the gastric glands can be distinguished from the Brunner<sup>1</sup> glands of the duodenum because the gastric glands lie in the tunica mucosa, that is, inside the muscularis mucosae, whereas the Brunner glands lie in the submucosa.

**VESSELS AND NERVES.** The arteries supplying the stomach are: the left gastric, the right gastric, and the right gastroepiploic branches of the hepatic artery, and the left gastroepiploic and short gastric branches of the lienal artery. They supply the muscular coat, ramify in the submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar. The arteries break up at the base of the gastric tubules into a plexus of fine capillaries that run upward between the tubules, anastomosing with each other and ending in a plexus of larger capillaries that surround the mouths of the tubes and also form hexagonal meshes around the ducts.

From these the **veins** arise, and pursue a straight course downward, between the tubules, to the submucous tissue; they end either in the lienal and superior mesenteric veins, or directly in the portal vein.

The **lymphatics** are numerous: they consist of a superficial and a deep set, and they pass to lymph nodes along the two curvatures of the organ.

The **nerves** are the terminal branches of the right and left vagi, the former usually being distributed upon the dorsal and the latter upon the ventral part of the organ. Numerous sympathetic fibers that arise chiefly from the various subdivisions of the celiac plexus accompany the different blood vessels to the organ. Small sympathetic filaments may also arise directly from the phrenic and splanchnic trunks. Nerve plexuses are found in the submucous coat and between the layers of the muscular coat, as in the intestine. From these plexuses, fibrils are distributed to the muscular tissue and the mucous membrane.

## **Small Intestine**

The **small intestine** extends from the pylorus to the ileocecal junction; it is about 7 meters long and gradually diminishes in diameter from its commencement to its termination. It is contained in the central and caudal part of the abdominal cavity and is surrounded cranially and at the sides by the

<sup>1</sup>Johann Konrad Brunner (1653-1727): A German anatomist (Heidelberg, then Strassburg).

**Fig. 16-71.** The longitudinal and circular muscle fibers of the stomach: anterior surface. (Redrawn after Spalteholz.)

large intestine; a portion of it extends below the superior aperture of the pelvis and lies ventral to the rectum. It is in relation, ventrally, with the greater omentum and abdominal parietes, and is connected to the vertebral column by a reduplication of peritoneum, the **mesentery**. The small intestine is divisible into three portions: the **duodenum**, the **jejunum**, and the **ileum**.

### DUODENUM

The duodenum (Fig. 16-57) received its name from being about equal in length to the breadth of 12 fingers (25 cm). It is the shortest, the widest, and the most fixed part of the small intestine, and it has no mesentery, being only partially covered by peritoneum. It has almost a circular course, so that its termination is not far removed from its starting point. For purposes of description the duodenum may be divided into four portions: **superior**, **descending**, **horizontal**, and **ascending**.

**SUPERIOR PORTION.** The superior portion is about 5 cm long, beginning at the pylorus and extending as far as the neck of the gallbladder. It is the most movable of the four portions. It is almost completely covered by peritoneum, but a small part of its posterior surface near the neck of the gallbladder and the inferior vena cava has no covering. The cranial border of its first half has the hepatoduodenal ligament attached to it; the caudal border is attached to the greater omentum. It is in such close relation with the gallbladder that it is usually stained by bile after death, especially on its ventral surface. It is in relation cranially with the quadrate lobe of the liver and the gallbladder; dorsally with the gastroduodenal artery, the common bile duct, and the portal vein; and caudally with the head and neck of the pancreas.

**DESCENDING PORTION.** The descending portion is 7 to 10 cm long and extends from the neck of the gallbladder, on a level with the first lumbar vertebra, along the right side of the vertebral column to the cranial border of the body of the fourth lumbar vertebra. It

**FIG. 16-72.** The oblique fibers of the stomach; anterior surface. (Redrawn after Spalteholz.)

is crossed in its middle third by the transverse colon, the posterior surface of which is not covered by peritoneum and is connected to the duodenum by a small quantity of connective tissue. The supra- and infracolic portions are covered ventrally by peritoneum (the infracolic part by the right leaf of the mesentery), but dorsally it is not covered by peritoneum. The descending portion is in relation ventrally with the gallbladder, the duodenal impression on the right lobe of the liver, and the transverse colon; dorsally, it has a variable relation to the right kidney in the neighborhood of the hilum and is connected to it by loose areolar tissue. The renal vessels, the inferior vena cava, and the psoas muscle are also dorsal to it. At its medial side are the head of the pancreas and the common bile duct; to its lateral side is the right colic flexure. The common bile duct and the pancreatic duct together perforate the medial side of this portion of the intestine 7 to 10 cm from the pylorus (Fig. 16-108); the accessory pancreatic duct sometimes pierces it about 2 cm proximal to this.

**HORIZONTAL PORTION.** The horizontal portion (*pars horizontalis*; third or *preaortic* or

*transverse* portion) is 5 to 7.5 cm long. It begins at the right side of the fourth lumbar vertebra and passes from right to left, with a slight inclination cranialward, ventral to the great vessels and crura of the diaphragm, and joins the ascending portion ventral to the abdominal aorta. It is crossed by the superior mesenteric vessels and the mesentery. Its ventral surface is covered by peritoneum, except near the midline, where it is crossed by the superior mesenteric vessels. Its posterior surface is not covered by peritoneum, except toward its left extremity, where the posterior layer of the mesentery may sometimes cover it to variable extents. This surface rests upon the right crus of the diaphragm, the inferior vena cava, and the aorta. The cranial surface is in relation with the head of the pancreas.

**ASCENDING PORTION.** The ascending portion (*pars ascendens*; fourth portion) of the duodenum is about 2.5 cm long. It ascends on the left side of the aorta as far as the level of the cranial border of the second lumbar vertebra, where it turns abruptly ventralward to become the jejunum and forms the **duodenojejunal flexure**. It lies ventral to the

**Fig. 16-73.** Stomach and small intestines after a barium meal. *a*, Barium has settled out of the fundus of the stomach; *b*, pylorus; *c*, eighth thoracic vertebra. (Department of Radiology, University of Pennsylvania.)

left psoas major muscle and left renal vessels, and it is covered ventrally and partly at the sides by peritoneum that is continuous with the left portion of the mesentery.

The superior part of the duodenum, as stated previously, is somewhat movable, but the rest is practically fixed and bound to neighboring viscera and the posterior abdominal wall by the peritoneum. In addition, the duodenojejunal flexure is held in place by a fibrous muscular band, the **musculus suspensorius duodeni** or **ligament of Treitz**.<sup>1</sup> This structure commences in the connective tissue around the celiac artery and right crus of the diaphragm, and passes caudalward to insert into the superior border of the duodenojejunal curve and a part of the ascending duodenum. It possesses, according to Treitz, smooth muscular fibers

mixed with the fibrous tissue of which it is principally composed (Haley and Peden, 1943). It has little importance as a muscle, but acts as a suspensory ligament.

**VESSELS AND NERVES.** The **arteries** supplying the duodenum are the right gastric and superior pancreaticoduodenal branches of the hepatic artery, and the inferior pancreaticoduodenal branch of the superior mesenteric artery.

The **veins** end in the lienal and superior mesenteric veins.

The **nerves** are derived from the celiac plexus.

## JEJUNUM AND ILEUM

The remainder of the small intestine is named **jejunum** and **ileum** (Fig. 16-52), the former term being given to the proximal two-fifths and the latter to the distal three-fifths. There is no morphologic line of distinction between the two and the division is arbitrary; the character of the intestine grad-

<sup>1</sup>Wenzel Treitz (1819-1872): An Austrian physician and professor of anatomy and pathology (Krakow and Prague).

usually undergoes a change so that a portion of the bowel taken from the first part of the jejunum would present characteristic and marked differences from the last part of the ileum.

**JEJUNUM.** The jejunum (*intestinum jejunum*) is wider, its diameter being about 4 cm, and its wall is thicker, more vascular, and of a deeper color than the ileum. The circular folds (*plicae circulares*; *valvulae conniventes*) of its mucous membrane are large and thickly set, and its villi are larger than those in the ileum. The aggregated lymph nodules are usually absent in the proximal part of the jejunum, and in the distal part they are found less frequently than in the ileum; they are also smaller and tend to assume a circular form. By grasping the jejunum between the finger and thumb, one can feel the circular folds through the walls, but this is not true of the lower part of the ileum; in this way it is possible to distinguish the upper from the lower part of the small intestine.

**ILEUM.** The ileum is narrower, its diameter being 3.75 cm, and its coats are thinner and less vascular than those of the jejunum. It possesses few circular folds, and they are small and disappear entirely toward its caudal end, but **aggregated lymph nodules** (Peyer's patches<sup>1</sup>) are larger and more numerous than in the jejunum. The jejunum for the most part occupies the umbilical and left iliac regions, whereas the ileum occupies chiefly the umbilical, hypogastric, right iliac, and pelvic regions. The terminal part of the ileum usually lies in the pelvis, from which it ascends over the right psoas muscle and right iliac vessels; it ends in the right iliac fossa by opening into the medial side of the commencement of the large intestine.

The jejunum and ileum are attached to the posterior abdominal wall by an extensive fold of peritoneum, the **mesentery**, which allows free motion so that each coil can accommodate itself to changes in form and position. The mesentery is fan-shaped; its posterior border, or root is about 15 cm long. It is attached to the posterior abdominal wall from the left side of the body of the second lumbar vertebra to the right sacroiliac articulation, crossing successively the horizontal part of the duodenum, the aorta, the inferior vena cava, the ureter, and the right psoas

muscle (Fig. 16-53). Its breadth between its vertebral and intestinal borders averages about 20 cm and is greater in the middle than at its ends. Between its two layers are blood vessels, nerves, lacteals, and lymph glands, together with a variable amount of fat.

**VARIATIONS.** **Meckel's diverticulum**<sup>2</sup> (*diverticulum ilei*) is the name given to a pouch that projects from the lower part of the ileum in about 2% of subjects. Its average position is about 1 meter proximal to the ileocecal valve, and its average length is about 5 cm. Its caliber is generally similar to that of the ileum, and its blind extremity may be free or connected with the abdominal wall or some other portion of the intestine by a fibrous band. It represents the remains of the proximal part of the vitelline duct, the duct of communication between the yolk sac and the primitive digestive tube in early fetal life.

## STRUCTURE OF THE SMALL INTESTINE

The internal surface has two types of irregularities or projections that are characteristic of the small intestine. They are the large **circular folds** and the minute **villi** (Figs. 16-74; 16-75).

The **circular folds** (*plicae circulares*; *valvulae conniventes*; *valves of Kerkring*<sup>3</sup>) (Fig. 16-74) are valvelike folds that project 3 to 10 mm into the lumen. The majority extend transversely around the inside of the cylinder of the intestine for about one-half to two-thirds of its circumference, but others complete the circle or form a spiral extending more than once around, even making two or three turns. The folds also have different heights, with high and low ones tending to alternate. The size and frequency of the folds are different in the three parts of the small intestine. The folds are formed by both the tela submucosa and the tunica mucosa. The core of submucosal connective tissue is firm, making these folds permanent structures that are not obliterated by distention, as are the transient rugae of the stomach.

The **villi** (Fig. 16-74) are tiny fingerlike projections, of a size just at the borderline of visibility with the naked eye, which are crowded together over the entire mucous

<sup>1</sup>Johann Conrad Peyer (1653-1712): A Swiss anatomist (Schaffhausen).

<sup>2</sup>Johann Friedrich Meckel (1781-1833): A German anatomist (Halle).

<sup>3</sup>Theodorus Kerckring (1640-1693): A German anatomist who worked in Amsterdam.

**Fig. 16-74.** Section through wall of small intestine (jejunum) of adult cadaver. 5  $\times$ .

surface, giving it a velvety appearance. They are irregular in size and shape, are larger in some parts of the intestine than in others, and become considerably flattened by distention of the intestine. The villi are composed entirely of tissue belonging to the tunica mucosa.

The wall of the small intestine is composed of four coats: **mucous**, **submucous**, **muscular**, and **serous**.

**MUCOUS MEMBRANE.** The mucous membrane is composed of the villi, the intestinal glands, a connective tissue framework, and muscularis mucosae. The surface epithelium covering the villi is a simple columnar type in which the majority of cells have a characteristic striated free border. Recent observations with the electron microscope have demonstrated that the striated appearance is due to innumerable closely set projections of

**Fig. 16-75.** A longitudinal section through the jejunum of a 24-year-old man, including section through two plicae circulares. c.m., circular muscle; i.g., intestinal gland; l.m., longitudinal muscle; l.n., lymphatic nodule; m.m., muscularis mucosae; p.c., plica circularis; t.m., tunica mucosa; v., villus. 15  $\times$ . (Sobotta.)

cytoplasm that are too small (diameter 0.08  $\mu\text{m}$ ) to be distinguished with the best light microscopes. Scattered liberally among the striated epithelial cells are numerous mucus-secreting goblet cells.

**Villi.** Each villus has a core of delicate areolar and reticular connective tissue that provides a basement membrane for the epithelium and supports the rich network of capillary blood vessels and the usually single lymphatic vessel (Fig. 16-76). The lymphatic capillary begins blindly near the tip of the villus, occupies a more or less central position, and opens into the lymphatic vessels in the submucosa. This central lymphatic capillary is called a **lacteal**, the name having been given because it is filled with a white milky fluid, known as chyle, during the digestion of a meal rich in fat. Scattered single strands of smooth muscle run parallel with the lacteal and appear to be extensions of the muscularis mucosae into the villus.

**Intestinal Glands.** The intestinal glands (crypts of Lieberkühn<sup>1</sup>) are simple tubular glands that open into the depressions between the villi and form a rather uniform layer of glandular tissue between the bases of the villi and the muscularis mucosae (Fig. 16-77). The striated surface epithelium and

goblet cells extend quite far down into the crypts, but at the bottom or fundus is a group of glandular secreting cells known as the **cells of Paneth**.<sup>2</sup> These cells contain large secretion granules that stain a bright red with eosin, and it is probable that they secrete the digestive enzymes of the small intestine. Mitotic divisions are frequently observed in the cells of the wall of the crypt and it is believed that proliferation of these cells replaces surface cells lost from natural attrition.

**Muscularis Mucosae.** The muscularis mucosae is a thin sheet of nonstriated muscle cells, composed of inner circular and outer longitudinal layers at the boundary between the mucosa and submucosa.

**SUBMUCOUS COAT.** The submucous coat is composed of fibroelastic and areolar connective tissue. It is a strong layer, forming the core of the circular folds. It contains the blood vessels and lymphatics that supply the mucous membrane and, near the muscularis, the **submucous nerve plexus of Meissner**<sup>3</sup> (Fig. 16-78). Small collections of lymphocytes and solitary lymphatic nodules may occur in any part of the small intestine;

<sup>1</sup>Johann Nathaniel Lieberkühn (1711-1756): A German anatomist (Berlin).

<sup>2</sup>Josef Paneth (1857-1890): An Austrian physician (Vienna).

<sup>3</sup>George Meissner (1829-1905): A German professor of anatomy and physiology (Basel and Göttingen).

**Fig. 16-76.** Villi of small intestine, showing blood vessels and lymphatic vessels. (Cadiat.)

**FIG. 16-77.** Intestinal glands (crypts of Lieberkühn) from human duodenum. *b.m.*, Basement membrane; *e.p.*, epithelium; *g.c.*, goblet cell; *lym.*, lymphocyte; *m.c.*, mast cell; *mi.*, mitosis; *s.b.*, striated border; *s.c.*, glandular-secreting cell (Paneth cell); *t.p.*, tunica propria. 300  $\times$ . (Sobotta.)

groups of nodules, known as Peyer's patches, occur in the ileum. The lymphatic nodules usually occupy the submucosa, infiltrate the muscularis mucosae, and extend out to the free surface, often appearing to obliterate some of the villi (Fig. 16-81).

**MUSCULAR COAT.** The muscular coat is composed of the usual two layers in the alimentary tube: outer longitudinal and inner circular. Between these two layers is a net of nervous tissue containing nonmyelinated nerve fibers and ganglion cells (Fig. 16-79) known as the myenteric or Auerbach's

**FIG. 16-78.** The nerve plexus of the submucosa from the rabbit. 50  $\times$ .

plexus.<sup>1</sup> The muscularis is somewhat thicker in the proximal than in the distal part of the intestine.

**SEROUS COAT.** The serous coat is composed of the peritoneum and the areolar connective tissue connecting it to the muscular coat. The small intestine is covered by peritoneum except along the narrow strip or border attached to the mesentery and the retroperitoneal parts of the duodenum.

**SPECIAL FEATURES. Duodenum.** The circular folds are not found in the first 2.5 to 5 cm beyond the pylorus, but in the descending part, distal to the openings of the bile and pancreatic ducts, they are especially large and numerous. The villi are also especially large and numerous in the duodenum. The common bile duct and the pancreatic duct pierce the left side of the descending portion about 7 to 10 cm from the pylorus (Fig. 16-108). At the opening of the ducts there is a thickening of their muscle coats commonly called the **sphincter of Oddi**<sup>2</sup> (*sphincter ampullae hepatopancreaticae*) which usually causes a protrusion, the **papilla of Vater**,<sup>3</sup> at the proximal end of a longitudinal fold. There is a slight depression

<sup>1</sup>Leopold Auerbach (1828-1897): A German professor of neuropathology (Breslau).

<sup>2</sup>Ruggero Oddi (19th century): An Italian physiologist (Perugia).

<sup>3</sup>Abraham Vater (1684-1751): A German professor of anatomy (Wittenberg).

**FIG. 16-79.** The myenteric plexus from the rabbit. 50  $\times$ .

and absence of the circular folds around the papilla (Fig. 16-80).

The **duodenal glands** (Brunner's glands<sup>1</sup>) differ from the other intestinal glands because they occupy the submucosa. The usual intestinal glands or crypts are found in the duodenum, and the ducts from the duodenal glands, after penetrating the muscularis mucosae, open into the bottoms of occasional crypts. The duodenal glands are compound tubuloalveolar glands; they resemble the pyloric glands of the stomach but are larger and, as mentioned, lie in the submucosa. The cells stain lightly in histologic preparations, but they give some of the reactions of mucus. The duodenal glands are largest and most numerous near the pylorus, forming there a rather thick complete layer, but they diminish in the horizontal portion and disappear near the duodenojejunal junction.

**Jejunum.** The circular folds and villi are almost as large and numerous in the proximal part of the jejunum as in the duodenum, but they gradually decrease in size and number toward the ileum.

**Ileum.** The circular folds and villi are smaller and less numerous in the ileum than in the jejunum, and toward the terminal part the folds may be widely scattered or even lacking.

**Aggregated lymphatic nodules** or **Peyer's patches** (Peyer's glands; *tonsillae intestinales*) are groups of lymphatic nodules

spread out as a single layer in the mucous membrane of the wall of the ileum opposite the mesenteric attachment (Fig. 16-81). The patches are circular or oval, approximately 1 cm wide, and may extend along the intestine for 3 to 5 cm. They are largest and most frequent in the distal ileum but are occasionally seen even in the jejunum. They can be recognized in gross specimens at autopsy as thickened whitish patches in which circular folds are absent and the villi are sparse or lacking. In the dissecting room, where the subjects are usually of advanced age, the patches are difficult to identify because of the atrophy of the lymphatic tissue that occurs in older individuals.

**VESSELS AND NERVES** The jejunum and ileum are supplied by the **superior mesenteric artery**, the intestinal branches of which, having reached the attached border of the bowel, run between the serous and muscular coats with frequent inosculations to the free border, where they also anastomose with other branches running around the opposite surface of the gut. From these vessels numerous branches are given off that pierce the muscular coat, supplying it and forming an intricate plexus in the submucous tissue. From this plexus minute vessels pass to the glands and villi of the mucous membrane. The **veins** have a course and arrangement similar to that of the arteries.

The **lymphatics** of the small intestine (lacteals) are arranged in two sets, those of the mucous membrane and those of the muscular coat. The lymphatics of the villi commence in these structures in the manner described above. They form an intricate plexus in the mucous and submucous tissue and are joined by the lymphatics from the lymph spaces at the bases of the solitary nodules; from this they pass

**Fig. 16-80.** Mucous membrane of the descending portion of the duodenum, showing the plica longitudinalis and the duodenal papilla (of Vater). (Redrawn from Spalteholz.)

to larger vessels at the mesenteric border of the gut. The lymphatics of the muscular coat are situated to a great extent between the two layers of muscular fibers, where they form a close plexus; throughout their course they communicate freely with the lymphatics from the mucous membrane, and empty in the same manner as these into the origins of the lacteal vessels at the attached border of the gut.

The **nerves** of the small intestine are derived from the plexuses of autonomic nerves around the superior mesenteric artery. They represent cranial parasympathetic fibers of the vagus and postganglionic sympathetic fibers from the celiac plexus. From this source they run to the **myenteric plexus** (*Auerbach's plexus*) (Fig. 16-79) of nerves and ganglia situated between the circular and longitudinal muscular fibers, from which the nervous branches are distributed to the muscular coats of the intestine. From this a secondary plexus, the **plexus of the submucosa** (*Meissner's plexus*) (Fig. 16-78) is derived, formed by branches that have perforated the circular muscular fibers. This plexus lies in the submucous coat of the intestine; it also contains ganglia from which nerve fibers pass to the muscularis mucosae and to the mucous membrane. The nerve bundles of the submucous plexus are finer than those of the myenteric plexus.

## Large Intestine

The **large intestine** (*intestinum crassum*) (Figs. 16-52; 16-53; 16-82; 16-83) extends from the ileum to the anus. It is about 1.5 meters

long, being one-fifth of the whole extent of the intestinal canal. Its caliber, when not unduly distended with feces, is largest at its commencement at the cecum and gradually diminishes as far as the rectum, where there is a dilatation of considerable size just above the anal canal. It differs from the small intestine in several ways: it has a sacculated form; it possesses certain appendages on its external coat, the **appendices epiploicae**; and its longitudinal muscular fibers are arranged in three **longitudinal bands or taeniae**.

The large intestine describes an arch around the convolutions of the small intestine. It commences in the right iliac region, ascends through the right lumbar and hypochondriac regions to the caudal surface of the liver, and there bends to the left to form the **right colic flexure**. It passes transversely across the epigastric and umbilical regions to the left hypochondriac region, where it bends caudalward, forming the **left colic flexure**, and descends through the left lumbar and iliac regions toward the pelvis. In the left iliac region it forms the **sigmoid flexure**, and from this it is continued along the posterior wall of the pelvis to the anus. The large intestine is divided into the **cecum**, **appendix**, **colon**, **rectum**, and **anal canal**.

**FIG. 16-82.** Large intestine after a barium enema. 1, Right colic flexure; 2, left colic flexure. The arrow points to the pelvic colon. Note the sacculations of the gut, and the different levels of the two flexures.

## CECUM

The **cecum** (*intestinum caecum*) (Fig. 16-84), the commencement of the large intestine, is the large blind pouch extending caudalward beyond the ileocecal valve. Its size is estimated variously by different authors, but on an average it is 6.25 cm long and 7.5 cm wide. It is situated in the right iliac fossa, cranial to the lateral half of the inguinal ligament. It rests on the iliacus muscle and usually lies in contact with the ventral abdominal wall, but the greater omentum and some coils of small intestine, if the cecum is empty, may lie ventral to it.

The common position of the cecum in the erect living body is not in the right iliac fossa but in the cavity of the true pelvis. As a rule, it is enveloped entirely by peritoneum, but in 5% of cases, part of the posterior surface is connected to the iliac fascia by connective tissue. The cecum lies quite free in the abdominal cavity and enjoys a considerable amount of movement, so that it may become herniated into the right inguinal canal, and

occasionally it has been found in an inguinal hernia on the left side.

The cecum varies in shape, but according to Treves, in man it may be classified as one of four types. In the first of his four types (about 2%), the cecum is conical and the appendix rises from its apex. The three longitudinal bands start from the appendix and are equidistant from each other. In the second type, the conical cecum has become quadrate because a saccule has grown out on either side of the anterior longitudinal band. These saccules are of equal size, and the appendix arises from between them, instead of from the apex of a cone (about 3%).

The third type is the normal type in man. In this case, the two saccules, which in the second type are uniform, have grown at unequal rates: the right with greater rapidity than the left. Consequently, an apparently new apex is formed by the caudalward growth of the right saccule, and the original apex, with the appendix attached, is pushed over to the left toward the ileocecal junction. The three longitudinal bands still start from

**FIG. 16-83.** Part of the large intestine after a barium meal. Note the vermiform appendix, which passes from the medial side of the cecum medially and slightly downward into the true pelvis. At a slightly higher level the terminal part of the ileum can be recognized. The first part of the transverse colon runs downward in front of, and slightly medial to, the ascending colon, before it turns to the left.

**FIG. 16-84.** The cecum and appendix, with their arteries.

the base of the vermiform appendix, but they are no longer equidistant from each other because the right sacculum has grown between the anterior and posterior bands, pushing them over to the left. This type occurs in about 90% of persons. The fourth type is merely an exaggerated condition of the third; the right sacculum is still larger and at the same time the left sacculum has become atrophied, so that the original apex of the cecum, with the vermiform appendix, is close to the ileocecal junction, and the anterior band courses medialward to the same location (about 4%).

**VERMIFORM APPENDIX.** The vermiform appendix (*processus vermiformis*) (Fig. 16-85) is a long, worm-shaped tube, 5 to 10 mm in diameter, which starts from what was originally the apex of the cecum. It may project in one of several directions: cranialward behind the cecum; to the left behind the ileum and mesentery; or caudalward into the lesser pelvis. It varies from 2 to 20 cm in

length, its average being about 8 cm. It is suspended by a peritoneal mesenteriole derived from the left leaf of the mesentery, which is more or less triangular in shape and usually extends along the entire length of the tube. Between its two layers and close to its free margin lies the appendicular artery (Fig. 16-84).

The lumen of the vermiform appendix is small, extends throughout the whole length of the tube, and communicates with the cecum by an orifice distal to the ileocecal opening. It is sometimes guarded by a semi-lunar valve formed by a fold of mucous membrane, but this is by no means constant.

**ILEOCECAL VALVE.** The ileum ends by opening into the medial part of the large intestine, at the junction of the cecum with the colon. The opening is guarded by a valve, the ileocecal valve (Fig. 16-85), which consists of two segments or lips that project into the lumen of the large intestine. If the intestine has been inflated and dried, the lips

**Fig. 16-85.** The cecum, colic valve, and vermiform appendix, with anterior wall of terminal ileum and cecum removed. (Eycleshymer and Jones.)

have a semilunar shape, one toward the colon, the other toward the cecum. At the ends of the aperture the two segments of the valve coalesce and continue as narrow membranous ridges around the canal for a short distance, forming the **frenula of the valve**. In the fresh condition or in specimens that have been hardened in situ, the lips project as thick cushion-like folds into the lumen of the large gut; the opening between them may have the appearance of a slit or may be somewhat oval.

## COLON

The colon is divided into four parts: the **ascending, transverse, descending, and sigmoid**.

**ASCENDING COLON.** The ascending colon passes cranialward from its commencement at the cecum to the caudal surface of the right lobe of the liver, where it is lodged in a shallow depression, the **colic impression**, to the right of the gallbladder; here it bends abruptly to the left, forming the **right colic (hepatic) flexure** (Fig. 16-53). It does not have a mesentery but is kept in contact with the posterior wall of the abdomen by the peritoneum, which covers its ventral surface and sides. Its dorsal surface is connected by loose areolar tissue with the iliacus and quadratus lumborum muscles, with the aponeurotic origin of transverse abdominal muscle, and with the ventral and lateral part of the right kidney. It is in relation, ventrally, with the convolutions of the ileum and the abdominal wall.

**TRANSVERSE COLON.** The transverse colon, the longest and most movable part of the colon, passes from the right colic flexure in the right hypochondriac region across the abdomen into the left hypochondriac region, where it curves sharply on itself beneath the caudal end of the spleen, forming the **left colic (splenic) flexure**. The transverse colon is festooned caudalward 7.5 to 10 cm below the interiliac line in most males in the erect posture, and 10 to 12.5 cm below in most females. It is completely invested by peritoneum, except for the **transverse mesocolon**, which is connected to the inferior border of the pancreas by a large duplicature of that membrane. It is in relation, by its cranial surface, with the liver and gallbladder, the greater curvature of the stomach, and the

spleen; by its caudal surface, with the small intestine; and by its ventral surface, with the anterior layers of the greater omentum and the abdominal wall. Its dorsal surface is in relation from right to left with the descending portion of the duodenum, the head of the pancreas, and some of the convolutions of the jejunum and ileum.

The **left colic or splenic flexure** (Fig. 16-53) occurs at the junction of the transverse and descending parts of the colon, and is in relation with the caudal end of the spleen and the tail of the pancreas. The flexure is so acute that the end of the transverse colon usually lies in contact with the front of the descending colon. Its position is more cranial and posterior to that of the right colic flexure. It is attached to the diaphragm opposite the tenth and eleventh ribs by a peritoneal fold, named the **phrenicocolic ligament**, which also assists in supporting the spleen.

**DESCENDING COLON.** The descending colon passes caudalward through the left hypochondriac and lumbar regions along the lateral border of the left kidney. At the caudal end of the kidney it turns medialward toward the lateral border of the psoas muscle and then descends, in the angle between the psoas and the quadratus lumborum muscles, to the crest of the ilium, where it becomes the iliac colon. The peritoneum covers its ventral surface and sides, while its dorsal surface is connected by areolar tissue with the caudal and lateral part of the left kidney, with the aponeurotic origin of the transversus abdominis, and with the quadratus lumborum muscle (Fig. 16-55). It is smaller in caliber and placed more deeply than the ascending colon and its posterior surface is more covered with peritoneum than is the ascending colon.

The part of the descending colon in the left iliac fossa may be called the **iliac colon** (Fig. 16-86). It is about 12 to 15 cm long. It begins at the level of the iliac crest, and ends in the sigmoid colon at the superior aperture of the lesser pelvis. It curves medialward ventral to the iliopsoas muscle and is covered by peritoneum on its sides and anterior surface only.

**SIGMOID COLON.** The sigmoid colon (*pelvic colon; sigmoid flexure*) (Fig. 16-86) forms a loop that averages about 40 cm in length and normally lies within the pelvis, but because of its freedom of movement, it may be

**Fig. 16-86.** Iliac colon, sigmoid or pelvic colon, and rectum seen from the front, after removal of pubic bones and bladder.

displaced into the abdominal cavity. It begins at the superior aperture of the lesser pelvis, where it is continuous with the iliac colon and forms one or two loops before it reaches the level of the third piece of the sacrum, where it bends downward and ends in the rectum. It is completely surrounded by peritoneum and is attached to the pelvic wall by an extensive mesentery, the **sigmoid mesocolon**, which gives it a considerable range of movement in its central portion. Dorsal to the sigmoid colon are the external iliac vessels, the left piriformis muscle, and the left sacral plexus of nerves; ventrally, some coils of the small intestine separate it from the bladder in the male and from the uterus in the female.

## RECTUM

The rectum (Fig. 16-87) is continuous with the sigmoid colon at the level of the third sacral vertebra; it passes caudalward, lying in the sacrococcygeal curve, and ends in the anal canal. It has two dorsoventral curves: a cranial, with its convexity dorsalward, and a

caudal, with its convexity ventralward. Two lateral curves are also described, one to the right, opposite the junction of the third and fourth sacral vertebrae, and the other to the left, opposite the left sacrococcygeal articulation; these, however, are of little importance. The rectum is about 12 cm long, and at its commencement its caliber is similar to that of the sigmoid colon, but near its termination it is dilated to form the **rectal ampulla**.

The rectum has no sacculations comparable to the haustrae of the colon, but when the lower part is contracted, its mucous membrane is thrown into longitudinal folds. There are certain permanent transverse folds that have a semilunar shape, **plicae transversales recti** (*Houston's valves*<sup>1</sup>) (Fig. 16-88). Usually there are three of these folds, but sometimes a fourth and occasionally only two are present. One is situated near the commencement of the rectum, on the right side; a second, about 3 cm beyond the first, extends inward from the left side of the tube; a third, the largest and most constant,

<sup>1</sup>John Houston (1802-1845): An Irish surgeon (Dublin).

**Fig. 16-87.** The posterior aspect of the rectum exposed by removing the lower part of the sacrum and the coccyx.

projects dorsalward, opposite the fundus of the urinary bladder. When a fourth is present, it is situated nearly 2.5 cm above the anus on the left and posterior wall of the tube. These folds are about 12 mm wide and contain some of the circular fibers of the gut. In the empty state of the intestine they overlap each other, as Houston remarks, "so effectually as to require considerable maneuvering to conduct a bougie or finger along the canal." Their function seems to be "to support the weight of fecal matter, and prevent its urging toward the anus, where its presence always excites a sensation demanding its discharge."

The peritoneum covers the ventral and lateral surface of the proximal two-thirds of the rectum, but distally it covers the ventral surface only, from which it is reflected onto

the seminal vesicles in the male and the posterior vaginal wall in the female.

The level at which the peritoneum is reflected from the rectum to the viscus ventral to it has considerable surgical importance in connection with the removal of the distal part of the rectum. In the male, the distance of the rectovesical excavation from the anus is about 7.5 cm (i.e., the height to which an ordinary index finger can reach). In the female, the rectouterine excavation is about 5.5 cm from the anal orifice. The rectum is surrounded by dense fascia loosely attached to the rectal wall by areolar tissue, that is, there is a fascial cleft that allows distention.

**RELATIONS OF THE RECTUM.** The proximal part of the rectum is in relation, dorsally, with the superior rectal vessels, the left piriformis muscle, and the left

**Fig. 16-88.** Coronal section of the rectum and anal canal showing the internal surface. (Redrawn after Sobotta.)

sacral plexus of nerves, which separate it from the pelvic surfaces of the sacral vertebrae; in its distal part it lies directly on the sacrum, coccyx, and levatores ani muscle, a dense fascia alone intervening. Ventrally, it is separated, in the male, from the fundus of the bladder and in the female, from the intestinal surface of the uterus and its appendages by some convolutions of the small intestine and frequently by the sigmoid colon. In the male, it is in relation with the triangular portion of the fundus of the bladder, the vesiculae seminales, the ductus deferentes, and more anteriorly the posterior surface of the prostate; in the female, it is in relation with the posterior wall of the vagina.

### ANAL CANAL

The anal canal (Figs. 16-87; 16-91; 16-92), or terminal portion of the large intestine, begins where the ampulla of the rectum narrows (at the level of the apex of the prostate in the male) and ends at the anus. It measures 2.5 to 4 cm long and forms an angle with the lower part of the rectum. It has no peritoneal covering, but is invested by the sphincter ani internus, supported by the levatores ani, and surrounded at its termination by the sphincter ani externus. Dorsal to it is a mass of muscular and fibrous tissue, the **anococcygeal body**; ventral to it, in the male, but separated by the perineal center, are the membranous portion of the urethra and bulb

of the penis and the fascia of the urogenital diaphragm. In the female it is separated from the lower end of the vagina by a mass of muscular and fibrous tissue named the **perineal body**.

The proximal half of the anal canal has vertical folds produced by an infolding of the mucous membrane around a plexus of veins, known as the **rectal columns** (of Morgagni<sup>1</sup>; Fig. 16-88). They are separated from each other by furrows (**rectal sinuses**), which end distally in small valve-like folds, termed **anal valves**, which join together the distal ends of the rectal columns. When these columns are swollen, and inflamed, they are known as hemorrhoids.

### STRUCTURE OF THE LARGE INTESTINE

The wall of the cecum and colon has certain characteristic folds and irregularities that show up most prominently on the internal surface. Unlike those in the small intestine, these folds include all four layers and may be seen on the external surface. The longitudinal bands of the muscular coat, which are described below, cause a puckering of the wall, so that between them it bulges into sacculations called **haustrae**. The wall between the haustrae is thrown into folds that have a crescentic form on the interior of the colon and are called the **semilunar folds**, in contrast with the circular folds of the small intestine.

The large intestine has four coats: **mucous**, **submucous**, **muscular**, and **serous**.

**MUCOUS COAT.** The mucous coat is smooth, that is, devoid of villi, and covers the inner surface of haustrae and semilunar folds in a coat of uniform thickness. The surface is covered with simple columnar epithelium containing large numbers of goblet cells. The glands of the large intestine are simple, straight, tubular glands containing the same type of epithelium as the surface; they are packed closely together and they open on the surface in tiny round holes that can readily be seen with a hand lens (Fig. 16-89). There is a delicate **muscularis mucosae** composed of inner circular and outer longitudinal fibers. Collections of lymphocytes and solitary lymphatic nodules occur

<sup>1</sup>Giovanni Battista Morgagni (1682–1771): An Italian professor of anatomy (Padua).

FIG. 16-89. Section through colon of adult cadaver. 5  $\times$ .

frequently, especially near the colic valve and in the rectum.

**SUBMUCOUS COAT.** The submucous coat is a rather uniform layer of areolar tissue containing blood and lymphatic vessels and connecting the mucosa with the muscularis.

**MUSCULAR COAT.** The muscular coat is composed of the usual inner circular and outer longitudinal layers of nonstriated muscle.

The circular fibers form a thin layer over the cecum and colon, which is somewhat thickened in the semilunar folds between the haustrae, uniformly thickened in the rectum, and in the anal canal, constitutes the strong circular nonstriated muscle, the **sphincter ani internus**.

The longitudinal muscle fibers are concentrated into three longitudinal bands that are equally spaced and about 12 mm wide. They are easily seen in a gross specimen (Fig. 16-53) and are called **taeniae coli**. They have specific positions in relation to the position of the colon itself: (1) the posterior taenia is placed along the attached border; (2) the anterior taenia is easily visible on the exposed surface of the ascending and descending colon, but is covered by the attachment of the greater omentum on the transverse colon; and (3) the lateral taenia is found on the medial side of the ascending and descending colon and on the dorsal aspect of the transverse colon. The anterior taenia is a useful guide for locating the position of the appendix vermiformis, because the latter is a direct extension from it (Fig. 16-84).

The taeniae are shorter than the other

coats of colon and cecum, causing the intervening wall to bulge into the sacculations known as **haustrae** which are typical of this part of the intestine (Fig. 16-52) and are responsible for the deep depressions in its outline in roentgenograms (Fig. 16-83). Between adjacent haustrae are the crescentic folds or plicae semilunares, which encroach on the lumen of the intestine.

**SEROUS COAT.** The serous coat, derived from the peritoneum, is complete over the cecum, appendix, transverse colon, and sigmoid colon except for their mesenteric attachments. It is incomplete on the rectum and on the ascending and descending colons where they are attached to the posterior abdominal wall.

**SPECIAL FEATURES. Ileocecal Valve.** Each lip of the valve is formed by a reduplication of the mucous membrane and the circular muscular fibers of the intestine. The longitudinal fibers and peritoneum are continued uninterruptedly from the small to the large intestine.

The surfaces of the valve directed toward the ileum are covered with villi and have the characteristic structure of the mucous membrane of the small intestine, while those turned toward the large intestine are destitute of villi and are marked with the orifices of the numerous tubular glands peculiar to the mucous membrane of the large intestine. These differences in structure continue as far as the free margins of the valve. It is generally maintained that this valve prevents reflux from the cecum into the ileum, but in all probability it acts as a sphincter around

the end of the ileum and prevents the contents of the ileum from passing too quickly into the cecum.

**Appendices Epiploicae.** The appendices epiploicae are characteristic features of the large intestine and may be used for its identification. They are small, round, irregular masses of fat, that average 0.5 to 1.0 cm in diameter, are almost completely covered by peritoneum, and are suspended from the surface of the colon and cecum by slender stalks (Fig. 16-89). They are usually attached along the taeniae, and are most numerous on the transverse colon.

**Vermiform Appendix or Process.** The appendix has the same four coats as the colon. The epithelial lining and the glands are similar, but the glands are much fewer and the mucosa and submucosa are much thickened and almost entirely occupied by lymphatic nodules and lymphocytes (Fig. 16-90). The longitudinal fibers of the tunica muscularis are evenly distributed, not arranged into taeniae as in the colon, and the circular muscle is more prominent than the longitudinal.

**Rectum.** The mucous membrane in the rectum is thicker and more vascular than that in the colon and is more loosely attached to the muscularis, as in the esophagus. The longitudinal fibers of the tunica muscularis are spread out into a layer that completely surrounds the rectum but is thicker on the anterior and posterior walls.

**Anal Canal.** The mucous membrane in the anal canal is thick and vascular. Beneath the longitudinal folds or **rectal columns** of Morgagni are dilated veins, often knotted and tortuous, where the tributaries of the superior and inferior rectal veins anastomose. The epithelium changes abruptly at about 1.5 to 2 cm above the anal opening; the transition is marked by a white line, below which the epithelium is stratified squamous that is continuous with the skin. In the region of this line are the openings of the **anal glands**, which are greatly enlarged, modified skin glands (Fig. 16-91).

The proper circular muscle layer, continuous with that of the rectum, is greatly thickened in the anal canal, forming the nonstriated **internal anal sphincter** (*sphincter ani internus*). In the tissue surrounding the anus is a circular ring of striated muscle, the **external anal sphincter**, and diverging from this to the walls of the pelvis is the **levator ani**. Just beneath the integument at the anal orifice is a more delicate striated muscle, the **corrugator cutis ani**; its fibers are closely associated with the tributaries of the inferior rectal veins draining the plexuses in the rectal columns, and spasm of its fibers may seriously retard the venous drainage.

**VESSELS AND NERVES** (Fig. 16-92). The **arteries** supplying the colon are derived from the colic and sigmoid branches of the mesenteric arteries. They give off large branches that ramify between and sup-

Fig. 16-90. Transverse section of human appendix. 20  $\times$ .

**Fig. 16-91.** Section of the rectum and anus of an adult cadaver. Lightly stained with hematoxylin. 5  $\times$ .

ply the muscular coats and, after dividing into small vessels in the submucous tissue, pass to the mucous membrane. The rectum is supplied by the superior rectal branch of the inferior mesenteric artery, and the anal canal is supplied by the middle rectal branch from the internal iliac artery and the inferior rectal branch from the internal pudendal artery. The superior rectal artery, the continuation of the inferior mesenteric, divides into two branches that run down either side of the rectum to within about 12.5 cm of the anus; they here split up into about six branches, which pierce the muscular coat and descend between it and the mucous membrane in the longitudinal direction, parallel with each other as far as the

sphincter ani internus, where they anastomose with the other rectal arteries and form a series of loops around the anus.

The **veins** of the rectum commence in a plexus of vessels that surrounds the anal canal. In the vessels forming this plexus are smaller saccular dilatations just within the margin of the anus; from the plexus about six large vessels are given off. These ascend between the muscular and mucous coats for about 12.5 cm, running parallel to each other; they then pierce the muscular coat (Fig. 16-92) and unite to form a single trunk, the superior rectal vein. This arrangement is termed the **rectal** or **hemorrhoidal plexus**; it communicates with the tributaries of the

**Fig. 16-92.** The blood supply of the rectum. A portion of the anterior wall has been cut away to show the rectal columns and the internal rectal (hemorrhoidal) plexus. (Eycleshymer and Jones.)

middle and inferior rectal veins at its commencement, thus establishing a communication between the systemic and portal circulations.

The **lymphatics** of the large intestine are described in Chapter 10.

The **nerves** to the region of the colon supplied by the superior mesenteric artery are derived in the same manner as those for the small intestine; nerves to the more distal portions of the colon and to the rectum are derived from sympathetic and sacral parasympathetic fibers through the inferior mesenteric and hypogastric plexuses. They are distributed in a similar way to those found in the small intestine.

## The Liver

The **liver** (*hepar*), the largest gland in the body, is situated in the cranial and right parts of the abdominal cavity, occupying

almost the whole of the right hypochondrium, the greater part of the epigastrium, and not uncommonly extending into the left hypochondrium as far as the mammary line.

**DEVELOPMENT OF THE LIVER.** The liver arises in the form of a diverticulum or hollow outgrowth from the ventral surface of that portion of the primitive gut which afterward becomes the descending part of the duodenum (Fig. 16-93). This diverticulum is lined by entoderm; it grows cranialward and ventralward into the septum transversum, which is a mass of mesoderm between the vitelline duct and the pericardial cavity. Two solid buds of cells that extend into the tissues represent the right and the left lobes of the liver. The solid buds of cells grow into columns or cylinders, termed the **hepatic cylinders**, which branch and anastomose to

**Fig. 16-93.** Liver with the septum transversum. Human embryo 3 mm long. (After model and figure by His.)

form a close meshwork. This network proceeds to invade the vitelline and umbilical veins, and eventually breaks up these vessels into a series of capillary-like vessels that ramify in the meshes of the cellular network and ultimately form the **sinusoids** of the liver.

The continued growth and ramification of the hepatic cylinders gradually produce the mass of the liver. The original diverticulum from the duodenum becomes the common bile duct, and from this the cystic duct and gallbladder arise as a solid outgrowth that later acquires a lumen. The opening of the common duct is at first in the ventral wall of the duodenum; later, owing to the rotation of the gut, the opening is carried to the left and then dorsalward to the position it occupies in the adult.

As the liver undergoes enlargement, both it and the ventral mesogastrium of the foregut are gradually differentiated from the septum transversum, and the liver projects caudalward into the abdominal cavity from the caudal surface of the septum transversum. By the growth of the liver, the ventral mesogastrium is divided into two parts, of which the ventral part forms the falciform and coronary ligaments and the dorsal part forms the lesser omentum. About the third month the liver almost fills the abdominal cavity, and its left lobe is nearly as large as its right.

From this period the relative development of the liver is less active, especially that of the left lobe, which actually undergoes some degeneration and becomes smaller than the right, but up to the end of fetal life the liver remains relatively larger than in the adult.

The **adult liver**, in the male, weighs 1.4 to 1.6 kg; in the female, 1.2 to 1.4 kg. It is relatively much larger in the fetus than in the adult, constituting in the former about one-eighteenth, and in the latter about one thirty-sixth of the entire body weight. Its greatest transverse measurement is 20 to 22.5 cm. Vertically, near its lateral or right surface, it measures about 15 to 17.5 cm; its greatest dorsoventral diameter, of 10 to 12.5 cm, is on a level with the cranial end of the right kidney. Opposite the vertebral column this measurement is reduced to about 7.5 cm. Its consistency is that of a soft solid; it is friable, easily lacerated and highly vascular; its color is dark reddish brown, and its specific gravity is 1.05.

The liver is irregularly hemispherical in shape, with an extensive, relatively smooth, convex diaphragmatic surface and a more irregular concave visceral surface. The diaphragmatic surface has four parts: ventral, superior, dorsal, and right. The human liver has four lobes: a large right lobe, a smaller left lobe, and much smaller caudate and quadrate lobes.

## SURFACES AND BORDERS

**DIAPHRAGMATIC SURFACE.** The diaphragmatic surface has the following portions: ventral, superior, dorsal, and right.

The **ventral or anterior portion** (Fig. 16-94) is separated by the diaphragm from the sixth to tenth ribs and their costal cartilages on the right side and from the seventh and eighth cartilages on the left. In the median region it lies dorsal to the xyphoid process and that part of the muscular anterior abdominal wall between the diverging costal margins. It is completely covered by peritoneum except along the line of attachment of the falciform ligament.

The **superior portion** (Fig. 16-95) is separated by the dome of the diaphragm from the pleura and lungs on the right and from the pericardium and heart on the left. The area near the heart is marked by a shallow concavity, the **cardiac fossa or impression**. The surface is mostly covered by peritoneum, but along its dorsal part it is attached to the

diaphragm by the superior reflection of the coronary ligament which separates the part covered with peritoneum from the so-called bare area.

The **dorsal or posterior portion** (Fig. 16-95) is broad and rounded on the right but narrow on the left. The central part presents a deep concavity that is molded to fit against the vertebral column and crura of the diaphragm; close to the right of this concavity the **inferior vena cava** lies almost buried in its **fossa**. Two or three centimeters to the left of the vena cava is the narrow **fossa for the ductus venosus**. The caudate lobe lies between these two fossae. To the right of the vena cava and partly on the visceral surface is a small triangular depressed area, the **suprarenal impression**, for the right suprarenal gland. To the left of the fossa for the ductus venosus is the **esophageal groove** for the antrum cardiacum of the esophagus.

A large part of the dorsal portion of the diaphragmatic surface is not covered by peritoneum; it is attached to the diaphragm by

Fig. 16-94. Ventral or anterior portion of diaphragmatic surface of the liver. (Redrawn from Rauber-Kopsch.)

FIG. 16-95. Superior portion of diaphragmatic surface of liver. (Redrawn from Rauber-Kopsch.)

loose connective tissue. The uncovered area, frequently called the **bare area**, is bounded by the superior and inferior reflections of the coronary ligament.

The **right portion** merges with the other three parts of the diaphragmatic surface and continues down to the right margin, which separates it from the visceral surface.

**VISCERAL SURFACE.** The visceral surface is concave, facing dorsalward, caudalward,

and to the left (Fig. 16-96). It contains several fossae and impressions for neighboring viscera. A prominent marking of the left central part is the **porta hepatis**, a fissure for the passage of the blood vessels and bile duct. The visceral surface is covered by peritoneum except where the gallbladder is attached to it and at the porta.

The right lobe, lying to the right of the gallbladder, has three impressions. Farthest

FIG. 16-96. Visceral surface of the liver. (Redrawn from Rauber-Kopsch.)

to the right is the **colic impression**, a flattened or shallow area for the right colic flexure; more dorsally a larger and deeper hollow is the **renal impression** for the right kidney, and the **duodenal impression** is a narrow and poorly marked area lying along the neck of the gallbladder. Between the gallbladder and **fossa for the umbilical vein** is the quadrate lobe. It is in relation with the pyloric end of the stomach, the superior portion of the duodenum, and the transverse colon.

The left lobe, lying to the left of the umbilical vein fossa, has two prominent markings. A large hollow extending out to the margin is the **gastric impression** for the ventral surface of the stomach. Toward the right it merges into a round eminence, the **tuber omentale**, which fits into the lesser curvature of the stomach and lies over the ventral surface of the lesser omentum. Just ventral to the inferior vena cava is a narrow strip of liver tissue, the **caudate process**, which connects the right inferior angle of the caudate lobe to the right lobe. Its peritoneal covering forms the ventral boundary of the epiploic foramen.

**INFERIOR BORDER.** The inferior border is thin and sharp, and marked opposite the attachment of the falciform ligament by a deep notch, the **umbilical notch**, and opposite the cartilage of the ninth rib by a second notch for the fundus of the gallbladder. In adult males this border generally corresponds with the lower margin of the thorax in the right mammary line, but in women and children it usually projects below the ribs. In the erect position it often extends below the interiliac line.

The **left extremity of the liver** is thin and flat from above downward.

## FISSURES AND FOSSAE

The **left sagittal fossa** (*longitudinal fissure*) is a deep groove in the visceral surface that extends from the notch on the inferior margin of the liver to the cranial border of the organ. It is not named in the *Nomina Anatomica* but is worthy of mention because it separates the right and left lobes. The porta joins it, at right angles, and divides it into two parts. The ventral part is the **fissure for the ligamentum teres**, which lodges the umbilical vein in the fetus and its re-

mains (the **ligamentum teres**) in the adult; it lies between the quadrate lobe and the left lobe of the liver, and is often partially bridged over by a prolongation of the hepatic substance, the **pons hepatis**. The dorsal part, or **fossa for the ductus venosus**, lies between the left lobe and the caudate lobe; it lodges the ductus venosus in the fetus, and in the adult, the **ligamentum venosum**, a slender fibrous cord that represents the obliterated remains of that vessel.

The **porta or transverse fissure** (Fig. 16-97) is a short but deep fissure, about 5 cm long, extending transversely across the visceral surface of the left portion of the right lobe, nearer its dorsal surface than its ventral border. It joins nearly at right angles with the left sagittal fossa and separates the quadrate lobe ventrally from the caudate lobe and process dorsally. It transmits the portal vein and the hepatic artery, nerves, duct, and lymphatics. The hepatic duct lies ventral and to the right; the hepatic artery, to the left; and the portal vein, dorsal to and between the duct and the artery.

The **fossa for the gallbladder** is a shallow, oblong fossa placed on the visceral surface of the right lobe, parallel with the left sagittal fossa. It extends from the inferior free margin of the liver, which is notched by it, to the right extremity of the porta.

The **fossa for the inferior vena cava** is a short, deep depression and occasionally a complete canal if the substance of the liver surrounds the vena cava. It lies on the posterior surface between the caudate lobe and the bare area of the liver, and is separated from the porta by the caudate process. The orifices of the hepatic veins perforate the floor of this fossa to enter the inferior vena cava.

## LOBES

**RIGHT LOBE.** The right lobe is six times as large as the left. It occupies the right hypochondrium, and is separated from the left lobe on its diaphragmatic surface by the falciform ligament, and on its visceral surface, by the left sagittal fossa. It has a somewhat quadrilateral form, its visceral and posterior surfaces being marked by three fossae: the porta and the fossae for the gallbladder and inferior vena cava, which separate its left part into two smaller lobes, the

**Fig. 16-97.** The gallbladder and portal area of the visceral surface of the liver with blood vessels and ducts exposed. (Redrawn from Rauber-Kopsch.)

**quadrate and caudate lobes.** The impressions on the right lobe have already been described.

**QUADRATE LOBE.** The quadrate lobe is situated on the visceral surface of the right lobe. It is bounded ventrally by the inferior margin of the liver; dorsally, by the porta; on the right, by the fossa for the gallbladder; and on the left, by the fossa for the umbilical vein. It has an oblong shape, with the dorsoventral diameter greater than the transverse diameter.

**CAUDATE LOBE.** The caudate lobe (*Spigelion lobe*<sup>1</sup>) is situated upon the dorsal surface of the right lobe of the liver, opposite the tenth and eleventh thoracic vertebrae. It is bounded inferiorly, by the porta; on the right, by the fossa for the inferior vena cava; and on the left, by the fossa for the ductus venosus. It is nearly vertical in position and

somewhat concave in the transverse direction. The **caudate process** is a small elevation of the hepatic substance that extends obliquely lateralward from the lower extremity of the caudate lobe to the visceral surface of the right lobe. It is situated dorsal to the porta and separates the fossa for the gallbladder from the commencement of the fossa for the inferior vena cava.

**LEFT LOBE.** The left lobe is smaller and flatter than the right. It is situated in the epigastric and left hypochondriac regions. Its cranial surface is slightly convex and is molded to the diaphragm; its caudal surface presents the gastric impression and omental tuberosity already mentioned.

#### INTERNAL LOBES AND SEGMENTS

The liver substance is divisible internally, on the basis of function and surgical importance, into lobes and segments that do not

<sup>1</sup>Adriaan van der Spiegel (1578–1625): A Flemish anatomist who worked in Padua.

coincide completely with the divisions established by external markings. These subdivisions must take into account the two great functions of the liver: (1) that of a gland, with the bile passages serving as its ducts, and (2) that of a vascular and storage organ. As a vascular organ it is necessary to devise units or segments including both inflow and outflow of blood, i.e., the branchings of both portal and hepatic veins. This is complicated by two facts: the portal veins have peripheral and the hepatic veins central positions in the lobules and greater subdivisions, and the portal vein has a bilateral type of distribution, whereas the hepatic veins have three main stems. It has been customary, however, to describe the internal lobes and segments on the basis of the portal venous radicles along with the bile ducts and to superimpose upon this a description based upon the hepatic venous radicles.

**HEPATIC TRIAD.** The three structures of the triad—bile duct, portal vein, and hepatic artery (Fig. 16-98)—gather in the hepatoduodenal ligament ventral to the epiploic fora-

men (of Winslow) at the porta hepatis. The hepatic duct is placed ventrally and to the right; the hepatic artery, to the left; and the portal vein, dorsally between the artery and duct. After their primary branching into right and left at the porta, they continue in a similar relationship throughout the organ. They are contained within a fibrous sheath, with prolongations to enclose their smallest branchings, called the **perivascular fibrous capsule** (Glisson's capsule) (Fig. 16-102).

The primary branching of the portal vein and hepatic artery at the porta establishes a right internal lobe and a left internal lobe. The **right internal lobe** comprises most of the right lobe of external marking described previously. It is subdivided into two segments; the **posterior segment** is more superior and somewhat larger than the **anterior segment**. Both segments are divided into superior and inferior portions.

The **left internal lobe** includes the left, the caudate, and the quadrate lobes of external marking. The division of the left lobe into a **medial segment** and a **lateral segment** is

**FIG. 16-98.** Intrahepatic distribution of the hepatic artery, portal vein, and biliary ducts. (From Morris' *Human Anatomy*, 12th edition, 1966. Courtesy of Blakiston Division of McGraw-Hill Book Company.)

marked on the surface by the attachment of the falciform ligament, the ligamentum teres, and the ligamentum venosum. The two segments have superior and inferior portions.

**VASCULAR SEGMENTS.** The three principal hepatic veins—right, middle, and left—provide the basis for classifying parts of the internal segments described above into **true vascular segments**: a right, a left, and two middle segments. A variable number of minor hepatic veins assist in the drainage of these vascular segments (Fig. 16-99).

The **right dorsal** or **dorsocaudal vascular segment** corresponds with the dorsal segment of the internal right lobe; it is drained by the right hepatic vein.

The **left lateral vascular segment** corresponds with the lateral segment of the left internal lobe; it is drained by the left hepatic vein.

The **ventral middle vascular segment** contains both the anterior segment of the right lobe and the medial segment of the internal

left lobe. It is drained by the middle hepatic vein.

The **dorsal middle vascular segment** contains the caudate lobe and caudate process, parts of the left internal lobe. It is drained usually by two minor hepatic veins, the cranial caudate hepatic vein and the caudal caudate hepatic vein.

## LIGAMENTS

The liver is connected to the undersurface of the diaphragm and to the ventral wall of the abdomen by five ligaments. Four of these—the **falciform**, the **coronary**, and the two **lateral ligaments**—are peritoneal folds; the fifth, the **round ligament**, is a fibrous cord that represents the obliterated umbilical vein. The liver is also attached to the lesser curvature of the stomach by the **hepatogastric ligament**, and to the duodenum by the **hepatoduodenal ligament**.

**Fig. 16-99.** Intrahepatic distribution of the hepatic and portal veins. (From Morris' *Human Anatomy*, 12th edition, 1966. Courtesy of Blakiston Division of McGraw-Hill Book Company.)

**FALCIFORM LIGAMENT.** The falciform ligament is situated in a parasagittal plane, but lies obliquely so that one surface faces ventralward and is in contact with the peritoneum dorsal to the right rectus muscle and the diaphragm, while the other is directed dorsalward and is in contact with the left lobe of the liver. It is attached by its left margin to the abdominal surface of the diaphragm, and the dorsal surface of the sheath of the right rectus as far caudalward as the umbilicus; by its right margin it extends from the notch on the inferior margin of the liver, as far dorsalward as the bare area. It is composed of two layers of peritoneum closely united together. Its base or free edge contains between its layers the round ligament and the parumbilical veins.

**CORONARY LIGAMENT.** The coronary ligament (*ligamentum coronarium hepatis*) consists of an anterior and a posterior layer. The anterior layer is formed by the reflection of the peritoneum from the cranial margin of the bare area of the liver to the undersurface of the diaphragm, and is continuous with the right layer of the falciform ligament. The posterior layer is reflected from the caudal margin of the bare area to the right kidney and suprarenal gland, and it is termed the **hepatorenal ligament**.

**TRIANGULAR LIGAMENTS.** There are two triangular ligaments (*lateral ligaments*): right and left.

The **right triangular ligament** is situated at the right extremity of the bare area, and is a small fold that passes to the diaphragm, being formed by the apposition of the anterior and posterior layers of the coronary ligament.

The **left triangular ligament** is a large fold that connects the posterior part of the upper surface of the left lobe to the diaphragm; its anterior layer is continuous with the left layer of the falciform ligament. It terminates on the left in a strong fibrous band, the **ap-  
pendix fibrosa hepatis**.

**ROUND LIGAMENT.** The round ligament (*ligamentum teres hepatis*) is a fibrous cord resulting from the obliteration of the umbilical vein. It ascends from the umbilicus in the free margin of the falciform ligament to the umbilical notch of the liver, from which it may be traced in its proper fossa on the inferior surface of the liver to the porta, where it becomes continuous with the *ligamentum venosum*.

## FIXATION OF THE LIVER

Several factors contribute to maintaining the liver in place. The attachments of the liver to the diaphragm by the coronary and triangular ligaments and the intervening connective tissue of the bare area, together with the intimate connection of the inferior vena cava by the connective tissue and hepatic veins, support the posterior part of the liver. The lax falciform ligament certainly gives no support, though it probably limits lateral displacement. During descent of the diaphragm with deep breathing, the liver rolls ventralward, shifting the inferior border caudalward so that it can be palpated.

## STRUCTURE OF THE LIVER

**VESSELS AND NERVES.** The vessels connected with the liver are the **hepatic artery**, the **portal vein**, and the **hepatic veins**.

The **hepatic artery** and **portal vein**, accompanied by numerous nerves, ascend to the porta between the layers of the lesser omentum. The **bile duct** and the lymphatic vessels descend from the porta between the layers of the same omentum. The relative positions of the three structures are as follows: the bile duct lies to the right, the hepatic artery to the left, and the portal vein dorsal to and between the other two (Fig. 16-108). They are enveloped in a loose areolar tissue, the **fibrous capsule of Glisson**, which accompanies the vessels in their course through the portal canals in the interior of the organ (Fig. 16-102).

The **hepatic veins** (Fig. 16-99) convey the blood from the liver and are described on page 836. They have little cellular investment, and what there is binds their walls closely to the walls of the canals through which they run, so that on section of the organ, they remain widely open and are solitary, and may be easily distinguished from the branches of the portal vein, which are more or less collapsed, and always accompanied by an artery and duct.

The **lymphatic vessels** of the liver are described under the lymphatic system (Chap. 10).

The **nerves** of the liver are derived from the right and left vagus and the celiac plexus of the sympathetic nerves. The fibers form plexuses along the hepatic artery and portal vein, enter the porta, and accompany the vessels and ducts to the interlobular spaces. The hepatic vessels are said to receive only sympathetic fibers, while both sympathetic and parasympathetic fibers are distributed to the walls of the bile ducts and gallbladder, where they form plexuses similar to the enteric plexuses of the intestinal wall.

## Parenchyma

The substance of the liver or parenchyma is composed of lobules held together by an extremely fine areolar tissue, in which ramify the portal vein, hepatic artery, hepatic veins, lymphatics, and nerves, the whole being invested by a serous and a fibrous coat.

**SEROUS COAT.** The serous coat is derived from the peritoneum and invests the greater part of the surface of the organ. It adheres intimately to the fibrous coat.

**FIBROUS COAT.** The fibrous coat lies beneath the serous investment and covers the entire surface of the organ. It is difficult to demonstrate, except where the serous coat is deficient. At the porta it is continuous with the fibrous capsule of Glisson, and on the surface of the organ, with the areolar tissue separating the lobules.

**LOBULES.** The lobules form the principal mass of the parenchyma. Their outlines, about 2 mm in diameter, give a mottled appearance to the surface of the organ. They are roughly hexagonal in shape, with their

columns of cells clustered around an intra-lobular vein, the smallest radicle of the hepatic vein. The adjacent faces of these neighboring hexagonal (or more irregularly polygonal) lobules are fitted together with a minimum of delicate connective tissue. In the pig, the individual lobules have complete connective tissue capsules and the hexagonal shape is more evident than in the human liver.

**PORTAL CANAL.** Portal canal is the name given to the channels through the parenchyma by which the smallest radicles of the portal vein, hepatic artery, and bile duct are distributed. These three are bound together by delicate connective tissue, the **capsula fibrosa perivascularis** or **Glisson's capsule**. They are situated between the lobules, and in a microscopic section cut perpendicularly through an intra-lobular vein, there will be three portal canals at the periphery of the lobule, about equally distant from each other at three angles of the hexagon. Polygonal shapes such as the hexagon in Figure 16-100 are common, however.

**FIG. 16-100.** Human liver lobule surrounded by parts of six neighboring lobules. (From Rauber-Kopsch, *Lehrbuch u. Atlas d. Anatomie d. Menschen*, 19th ed., Vol. II, courtesy Georg Thieme Verlag, Stuttgart, 1955.)

### Microscopic Appearance

Each lobule consists of a mass of **hepatic cells** arranged in irregular radiating columns and plates, between which are the blood channels (sinusoids) (Fig. 16-100). Between the cells are also minute bile capillaries. Therefore, each lobule has all the essentials of a secreting gland: (1) **cells** by which the secretion is formed; (2) **blood vessels** in close relation with the cells, containing the blood from which the secretion is derived; (3) **ducts**, by which the secretion, when formed, is carried away.

**HEPATIC CELLS.** The hepatic cells are polyhedral. They vary in size from 12 to 25  $\mu\text{m}$  in diameter. They contain one or sometimes two distinct nuclei. The nucleus exhibits an intranuclear network and one or two refractile nucleoli. The cells usually contain granules, some of which are protoplasmic, while others consist of glycogen, fat, or an iron compound. In lower vertebrates such as the frog, the cells are arranged in tubes with the bile duct forming the lumen and the blood vessels located externally.

**BLOOD VESSELS.** The blood in the capillary plexuses around the liver cells is brought to the liver principally by the portal vein, but also to a certain extent by the hepatic artery.

The **hepatic artery**, which enters the liver at the porta with the portal vein and hepatic duct, ramifies with these vessels through the

portal canals. It gives off **vaginal branches**, which ramify in the fibrous capsule of Glisson and appear destined chiefly for the nutrition of the coats of the vessels and ducts. It also gives off **capsular branches**, which reach the surface of the organ, ending in its fibrous coat in stellate plexuses. Finally, it gives off **interlobular branches**, which form a plexus outside each lobule to supply the walls of the interlobular veins and the accompanying bile ducts. From these plexuses, capillaries join directly with the sinusoids of the liver lobule at its periphery.

The **portal vein** also enters at the porta and runs through the portal canals (Fig. 16-99) enclosed in Glisson's capsule. In its course it divides into branches, which finally break up into the **interlobular plexuses** in the interlobular spaces. These interlobular plexuses give off portal venules, which divide into small branches and twigs as they pass to the surfaces of the lobules to join the hepatic sinusoids (Fig. 16-101).

**Hepatic sinusoids** are large, richly anastomosing, modified capillary channels lying between the cords of liver cells. They traverse the liver lobule from its periphery to the intralobular or central vein. At the periphery of the lobule they connect with interlobular branches of the portal vein and hepatic artery. Thus all the blood that enters the liver passes through the sinusoids to the central veins. The sinusoids are lined by

**FIG. 16-101.** Bile capillaries in the liver of a rabbit demonstrated by silver chromate, counterstained with aluminocarmine. (From Rauber-Kopsch, *Lehrbuch u. Atlas d. Anatomie d. Menschen*, 19th ed., Vol. II, courtesy Georg Thieme Verlag, Stuttgart, 1955.)

modified endothelium and contain many macrophages (v. Kupffer cells)<sup>1</sup> attached to their walls.

**HEPATIC VEINS.** At the center of the lobule, the sinusoids empty into one large vein that runs down the center of the lobule from apex to base; this is called the **intralobular** or **central vein**. At the base of the lobule this vein opens directly into the **sublobular vein**, with which the lobule is connected. The sublobular veins unite to form larger and larger trunks, and end at last in the hepatic veins; these converge to form three large trunks that open into the inferior vena cava while that vessel is situated in its fossa on the posterior surface of the liver.

**BILE DUCTS.** The bile ducts commence by little passages in the liver cells that communicate with canaliculi termed **intercellular biliary passages** (bile capillaries). These passages are merely little channels or spaces left between the contiguous surfaces of two cells or in the angle where three or more liver cells meet (Fig. 16-101). They are always separated from the blood capillaries by at least half the width of a liver cell. The channels thus formed radiate to the circumference of the lobule and open into the interlobular bile ducts, which run in Glisson's capsule, accompanying the portal vein and hepatic artery (Fig. 16-102). These join with other ducts to form two main trunks that leave the liver at the porta, and by their union form the **hepatic duct**.

<sup>1</sup>Karl Wilhelm von Kupffer (1829-1902): A German anatomist (Kiel, Königsberg and Munich).

**Structure of the Ducts.** The walls of the biliary ducts consist of a connective tissue coat that contains muscle cells arranged both circularly and longitudinally, and an epithelial layer that consists of short columnar cells resting on a distinct basement membrane.

#### EXCRETORY APPARATUS OF THE LIVER

The excretory apparatus of the liver consists of (1) the **hepatic duct**, formed by the junction of the two main ducts, which pass out of the liver at the porta; (2) the **gallbladder**, which serves as a reservoir for the bile; (3) the **cystic duct**, or the duct of the gallbladder; and (4) the **common bile duct**, which is formed by the junction of the hepatic and cystic ducts.

##### Hepatic Duct

Two main trunks of nearly equal size, one from the right, the other from the left lobe, unite to form the hepatic duct (Fig. 16-98), which passes to the right for about 4 cm between the layers of the lesser omentum, where it is joined at an acute angle by the cystic duct to form the common bile duct. The hepatic and part of the common duct are accompanied by the hepatic artery and portal vein.

##### Gallbladder

The gallbladder (*vesica fellea*) (Fig. 16-103) is a conical or pear-shaped musculo-membranous sac lodged in a fossa on the vis-

**FIG. 16-102.** Cross section of a portal canal with Glisson's capsule of interlobular connective tissue surrounding branches of the portal vein, hepatic artery, and hepatic duct. (From Rauber-Kopsch, *Lehrbuch u. Atlas d. Anatomie d. Menschen*, 19th ed., Vol. II, courtesy Georg Thieme Verlag, Stuttgart, 1955.)

**FIG. 16-103.** The gallbladder and bile ducts laid open. (Spalteholz.)

ceral surface of the right lobe of the liver and extending from near the right extremity of the porta to the inferior border of the organ. It is 7 to 10 cm in length, 2.5 cm in breadth at its widest part, and holds from 30 to 35 ml of bile. It is divided into a fundus, body, and neck. The **fundus**, or broad extremity, is directed caudalward and projects beyond the inferior border of the liver; the **body** and **neck** are directed cranialward and dorsalward to the left. The surface of the gallbladder is attached to the liver by connective tissue and vessels. The caudal surface is covered by peritoneum, which is reflected on to it from the surface of the liver. Occasionally the whole of the organ is invested by the serous membrane and is then connected to the liver by a kind of mesentery.

**RELATIONS.** The **body** is in relation with the commencement of the transverse colon and farther dorsally usually with the descending portion of the duodenum, but sometimes with the superior portion of

the duodenum or pyloric end of the stomach. The **fundus** is in relation, ventrally, with the abdominal parietes immediately below the ninth costal cartilage, and dorsally with the transverse colon. The **neck** is narrow and curves upon itself like the letter S; at its point of connection with the cystic duct it presents a well-marked constriction.

**STRUCTURE OF THE GALLBLADDER.** The gallbladder consists of three coats: **serous**, **fibromuscular**, and **mucous** (Fig. 16-104).

**Serous Coat.** The external or serous coat is derived from the peritoneum; it completely invests the fundus, but covers the body and neck only on their caudal surfaces.

**Fibromuscular Coat.** The fibromuscular coat, a thin but strong layer forming the framework of the sac, consists of dense fibrous tissue that interlaces in all directions and is mixed with smooth muscular fibers, which are disposed chiefly in a longitudinal direction with a few running transversely.

**Mucous Coat.** The internal or mucous coat is loosely connected with the fibrous layer. It is generally yellowish-brown and is elevated into minute rugae. Opposite the neck of the gallbladder the mucous membrane projects inward in oblique ridges or folds, forming a sort of spiral valve.

The mucous membrane is continuous through the hepatic duct with the mucous membrane that lines the ducts of the liver, and through the common bile duct with the mucous membrane of the duodenum. It is covered with high columnar epithelium and secretes mucin; in some animals it secretes a nucleoprotein instead of mucin.

**VESSELS AND NERVES.** The **arteries** to the gallbladder are derived from the cystic artery; its **veins** drain into liver capillaries and into the portal vein. The **lymphatics** are described under the lymphatic system. The **nerves** are described on page 1270.

### Cystic Duct

The cystic duct, about 4 cm long, runs dorsalward, caudalward, and to the left from the neck of the gallbladder; it joins the hepatic duct to form the common bile duct. The mucous membrane lining its interior is thrown into a series of 5 to 12 crescentic folds similar to those found in the neck of the gallbladder. They project into the duct in regular succession, and are directed obliquely around the tube, presenting the ap-

**FIG. 16-104.** Cross section through the wall of the human gallbladder. (From Rauber-Kopsch, *Lehrbuch u. Atlas d. Anatomie d. Menschen*, 19th ed., Vol. II, courtesy Georg Thieme Verlag, Stuttgart, 1955.)

pearance of a continuous spiral valve. They constitute the **spiral valve** (of Heister<sup>1</sup>), which is found only in primates and represents a device to prevent distention or collapse of the cystic duct due to changing pressures in the gallbladder or common duct associated with the assumption of an erect posture. When the duct is distended, the spaces between the folds are dilated, giving its exterior a twisted appearance.

### Common Bile Duct

The common bile duct (*ductus choledochus*) (Fig. 16-108) is formed by the junction of the cystic and hepatic ducts; it is about 7.5 cm long and has the diameter of a soda fountain straw.

It descends along the right border of the lesser omentum dorsal to the superior portion of the duodenum, ventral to the portal vein and to the right of the hepatic artery. It

then runs in a groove near the right border of the posterior surface of the head of the pancreas; here it is situated ventral to the inferior vena cava and is occasionally completely embedded in the pancreatic substance. At its termination it is closely associated with the terminal portion of the pancreatic duct as it passes obliquely through the muscular and mucous coats of the duodenum. The walls of the terminal portions of both ducts are thickened by the presence of a sphincter muscle, the sphincter of Oddi, which usually causes a protrusion into the lumen of the duodenum, the **duodenal papilla** or papilla of Vater. A common orifice for the two ducts is present in about 60% of persons, and separate openings in about 40%. The ducts become narrower rather than wider as they traverse the papilla, and the length of common channel shared by bile and pancreatic ducts is less than one half the papilla in 75% of persons. The term "ampulla of Vater" should therefore be discarded in favor of the "papilla of Vater" (Sterling, 1954).

**STRUCTURE.** The coats of the large biliary ducts are **external** or **fibrous** and **internal** or **mucous**. The **fibrous coat** is composed of strong fibroareolar tissue, with a certain amount of muscular tissue arranged, for the most part, in a circular manner around the duct. The **mucous coat** is continuous with the lining membrane of the hepatic ducts and gallbladder and also with that of the duodenum; like the mucous membrane of these structures, its epithelium is columnar. It is provided with numerous mucous glands that are lobulated and open by minute orifices scattered irregularly in the larger ducts.

## The Pancreas

The **pancreas** (Fig. 16-57) is situated transversely across the posterior wall of the abdomen, in the epigastric and left hypochondriac regions. Its length varies from 12.5 to 15 cm; its weight in the female is  $84.88 \pm 14.95$  gm and in the male,  $90.41 \pm 16.08$  gm (Schaefer, 1926).

### DEVELOPMENT

The pancreas is developed in two parts, dorsal and ventral (Figs. 16-105; 16-106). The former arises as a diverticulum from the dor-

<sup>1</sup>Lorenz Heister (1683-1758): A German anatomist and surgeon (Helmstadt).

FIG. 16-105. Pancreas of a human embryo of five weeks. (Kollmann.)

sal aspect of the duodenum a short distance above the hepatic diverticulum, and growing cranialward and dorsalward into the dorsal mesogastrium, it forms a part of the head and uncinate process and the whole of the body and tail of the pancreas. The ventral part appears as a diverticulum from the primitive bile duct and forms the remainder of the head and uncinate process of the pancreas. The duct of the dorsal part (**accessory pancreatic duct**) therefore opens independently into the duodenum, while that of the ventral part (**pancreatic duct**) opens with the common bile duct. About the sixth week the two parts of the pancreas meet and fuse and a communication is established between their ducts. After this has occurred, the terminal part of the accessory duct, i.e., the part between the duodenum and the point of meeting of the two ducts, undergoes little or no enlargement, while the pancreatic duct increases in size and forms the main duct of the gland. The opening of the accessory duct into the duodenum is sometimes obliterated, and even when it remains patent it is proba-

FIG. 16-106. Pancreas of a human embryo at end of sixth week. (Kollmann.)

ble that the whole of the pancreatic secretion is conveyed through the pancreatic duct.

At first the pancreas lies between the two layers of the dorsal mesogastrium, which give it a complete peritoneal investment, and its surfaces look to the right and left. With the change in the position of the stomach, the dorsal mesogastrium is drawn caudalward and to the left, and the right side of the pancreas is directed dorsalward and the left side, ventralward. The right surface becomes applied to the posterior abdominal wall, and the peritoneum that covered it undergoes absorption; thus, in the adult, the gland appears to lie behind the peritoneal cavity.

The **adult pancreas** is a compound racemose gland, analogous in its structures to the salivary glands, though softer and less compactly arranged than those organs. Its shape is long and irregularly prismatic; its right extremity, being broad, is called the **head**, which is connected to the main portion of the organ, or **body**, by a slight constriction, the **neck**, while its left extremity gradually tapers to form the **tail**.

## HEAD

The head of the pancreas is lodged within the curve of the duodenum (Fig. 16-107). Its cranial border is overlapped by the superior part of the duodenum and its caudal border overlaps the horizontal part of the duodenum; its right and left borders overlap and insinuate themselves around the descending and ascending parts of the duodenum respectively. The angle of junction of the caudal and left lateral borders forms a prolongation, termed the **uncinate process**. In the groove between the duodenum and the right lateral and caudal borders are the anastomosing superior and inferior pancreaticoduodenal arteries (Fig. 8-58); the common bile duct descends to its termination in the descending part of the duodenum close to the right border.

The greater part of the right half of the **anterior surface** is in contact with the transverse mesocolon, with only areolar tissue intervening. From its cranial part the **neck** springs, its right limit being marked by a groove for the gastroduodenal artery. The caudal part of the right half, below the transverse colon, is covered by peritoneum that is continuous with the inferior layer of the

**Fig. 16-107.** Transverse section through the middle of the first lumbar vertebra, showing the relations of the pancreas. (Braune.)

transverse mesocolon, and it is in contact with the coils of the small intestine. The superior mesenteric artery passes down ventral to the left half across the uncinate process; the superior mesenteric vein runs cranialward on the right side of the artery and, dorsal to the neck, joins with the lienal vein to form the portal vein (Fig. 9-33).

The **posterior surface** is in relation with the inferior vena cava, the common bile duct, the renal veins, the right crus of the diaphragm, and the aorta.

### NECK

The neck is about 2.5 cm long, and is directed at first ventralward and then to the left to join the body. Its ventral surface supports the pylorus; its dorsal surface is in relation with the commencement of the portal vein. On the right it is grooved by the gastroduodenal artery.

### BODY

The body has a prismatic shape and three surfaces: **anterior**, **posterior**, and **inferior**; and three borders: **superior**, **anterior**, and **inferior**.

The **anterior surface** is somewhat concave and is covered by the dorsal surface of the stomach, which rests upon it; the two organs are separated by the omental bursa. Where it joins the neck there is a well-marked prominence, the **tuber omentale**, which abuts against the posterior surface of the lesser omentum.

The **posterior surface** is devoid of peritoneum and is in contact with the aorta, the lienal vein, the left kidney and its vessels, the left suprarenal gland, the origin of the superior mesenteric artery, and the crura of the diaphragm.

The **inferior surface** is narrow on the right but broader on the left and is covered by peritoneum. It is in contact with the duodenojejunal flexure and some coils of the jejunum. Its left extremity rests on the left colic flexure.

The **superior border** is blunt and flat to the right and narrow and sharp to the left near the tail. It commences on the right in the omental tuberosity and is in relation with the celiac artery, from which the hepatic artery courses to the right just above the gland, while the lienal artery runs toward the left in a groove along this border.

The **anterior border** separates the anterior surface from the inferior surface, and along

this border the two layers of the transverse mesocolon diverge from each other, one passing over the anterior surface, the other over the inferior surface.

The **inferior border** separates the posterior surface from the inferior surface. The superior mesenteric vessels emerge under its right extremity.

## TAIL

The tail is the narrow part extending to the left as far as the caudal part of the gastric surface of the spleen. It lies in the phrenicocolic ligament and is in contact with the left colic flexure.

## PANCREATIC DUCT

The pancreatic duct (*duct of Wirsung*<sup>1</sup>) extends transversely through the substance of the pancreas (Fig. 16-108). It commences by the junction of the small ducts of the lobules situated in the tail of the pancreas, and running from left to right through the body, it receives the ducts of the various lobules composing the gland. It reaches the neck considerably augmented in size, and turning caudalward, dorsalward, and to the right, it comes into relation with the common bile duct, which lies to its right side. Leaving the

<sup>1</sup>Johann Georg Wirsung (1600-1643): A German anatomist who worked in Padua.

**FIG. 16-108.** The pancreas, pancreatic duct, and neighboring structures. (Eycleshymer and Jones.)

head of the gland, it passes very obliquely through the muscular and mucous coats of the duodenum and ends by an orifice common to it and the common bile duct upon the summit of the duodenal papilla, which is situated at the medial side of the descending portion of the duodenum, 7.5 to 10 cm below the pylorus. In 40% of bodies the pancreatic duct and the common bile duct open separately into the duodenum. Frequently an additional duct is given off from the pancreatic duct in the neck of the pancreas; this opens into the duodenum about 2.5 cm above the duodenal papilla. It receives the ducts from the lower part of the head and is known as the **accessory pancreatic duct** (duct of Santorini<sup>1</sup>).

**FUNCTION.** The pancreas is a gland of both external (exocrine) and internal (endocrine) secretion. The greater part of its bulk is formed by the exocrine gland. Its secretion, the **pancreatic juice**, is conveyed by the pancreatic duct to the duodenum, where its several enzymes aid in the digestion of proteins, carbohydrates, and fats. The endocrine gland is formed by small clumps of cells known as islets of Langerhans<sup>2</sup> scattered throughout the pancreas. The secretion of these cells, called **insulin**, is taken up by the bloodstream and is an important factor in the control of sugar metabolism in the body.

### STRUCTURE OF THE PANCREAS

**EXOCRINE PANCREAS.** The exocrine pancreas is a compound tubulo-acinar or racemose gland, resembling the parotid gland in microscopic structure. It has a connective tissue covering but no distinct capsule. It is made up of lobes and lobules that are identifiable but indistinctly marked with connective tissue in the human pancreas.

The main **pancreatic duct** extends throughout the length of the gland, receiving smaller ducts from the lobes and lobules along its course (Fig. 16-108). Although two ducts are formed in the embryo, they are usually combined into a single system in the adult. The main duct is lined with cylindrical epithelium containing occasional goblet cells; the smaller intermediate and intercalated ducts have lower cuboidal cells.

The **secreting acini** are almost filled by the

protruding apices of the glandular cells, which are the serous or zymogenic type. The basal portion of these cells, resting on a basement membrane, contains the nucleus and a **basophilic substance**, which has a striated appearance and is identified as the cytoplasmic reticulum by the electron microscope. The apical portion of these cells contains **zymogen granules**, easily seen in the usual eosin-stained preparations because of their red color. During digestion the granules become reduced in number. A characteristic feature of the pancreas is the presence of **centroacinar cells**. They represent a continuation of the terminal duct into the secreting acini. They are smaller than the secreting cells and have a clear cytoplasm (Munger, 1958; Oram, 1955).

**ENDOCRINE PANCREAS.** The **islets of Langerhans** can be identified in the usual histological preparations as clusters of less deeply stained cells. They are scattered throughout the gland but usually appear near the center of a lobule (Fig. 16-109). The cells are arranged in cords or plates one or two cells thick between which are abundant capillaries. There are three types of cells, which can be demonstrated by the use of special stains: **alpha cells**, **beta cells**, and **delta cells**. The beta cells are most abundant and are the source of insulin (Ferner, 1952; Lacy, 1957).

**Fig. 16-109.** Section of portion of lobule from human pancreas. *ac.*, Acinus of exocrine secreting gland; *b.v.*, blood vessel; *c.a.*, centroacinar cells; *i.l.*, islet of endocrine-secreting cells (islet of Langerhans). 200  $\times$ . (Redrawn from Sobotta.)

<sup>1</sup>Giovanni Domenico Santorini (1681-1737): An Italian anatomist (Venice).

<sup>2</sup>Paul Langerhans (1847-1888): A German anatomist and pathologist (Freiburg).

**VESSELS.** The arteries of the pancreas are mainly branches of the splenic artery, which form several arcades with the pancreatic branches of the gastroduodenal and superior mesenteric arteries (Michels, 1955). The veins are tributaries of the splenic and superior mesenteric portions of the portal vein. The lymphatics drain into the regional nodes associated with the major arteries to the gland.

**NERVES.** The autonomic innervation is both parasympathetic and sympathetic through the splenic subdivision of the celiac plexus. The sympathetic nerves are postganglionic; the parasympathetic nerves are preganglionic nerves from the vagus, which synapse with ganglion cells scattered throughout the gland. Sensory nerves to the pancreas are conveyed mainly by way of the splanchnic nerves (Alvarado, 1955).

## The Urogenital System

Urogenital or genitourinary is the term used for the system of **urinary organs**, which provide for the formation and discharge of the urine, and for the **genital organs**, which are concerned with the process of reproduction.

### Development of Urinary Organs

The urogenital glands and ducts develop from the intermediate cell mass situated between the primitive segments and the lateral plates of mesoderm. The permanent organs of the adult are preceded by structures which, with the exception of the ducts, disappear almost entirely before the end of fetal life. These paired structures are: the **pronephros**, the **mesonephros**, and the **mesonephric** and **paramesonephric ducts**. The pronephros disappears very early. The structural elements of the mesonephros degenerate almost entirely, but in their place the genital gland develops. The mesonephric duct remains as the duct of the male genital

gland; the paramesonephric, as that of the female. The final kidney is a new organ, the **metanephros**.

### PRONEPHROS AND MESONEPHRIC DUCT

In the lateral part of the intermediate cell mass, immediately under the ectoderm, in the region from the fifth cervical to the third thoracic segments, a series of short evaginations from each segment grows dorsolaterally and caudally, fusing successively caudward to form the **pronephric duct** (Fig. 17-1). This continues to grow caudally until it opens into the ventral part of the cloaca; beyond the pronephros it is termed the **mesonephric** or **Wolffian duct**.<sup>1</sup>

The original evaginations form a series of transverse tubules, each of which communicates by means of a funnel-shaped ciliated opening, the **nephrostome**, with the coelomic cavity, and in the course of each duct a **glomerulus** also is developed. A secondary glomerulus is formed ventral to each of these, and the complete group constitutes the **pronephros**. The pronephros undergoes rapid atrophy and, in 4-mm embryos, disappears except for the pronephric ducts, which persist as the excretory ducts of the succeeding kidneys, the mesonephroi.

### MESONEPHROS

On the medial side of the mesonephric duct, from the sixth cervical to the third lumbar segments, a series of **mesonephric tubules** develops; at a later stage in the development they increase in number by outgrowths from the original tubules (Fig. 17-1). These tubules first appear as solid masses of cells that later develop a lumen; one end grows toward and finally opens into the mesonephric duct, the other dilates and is invaginated by a tuft of capillary blood vessels to form a glomerulus. The tubules collectively constitute the **mesonephros** or **Wolffian body**. By the fifth or sixth week this body produces an elongated spindle-shaped eminence termed the **urogenital fold**, which projects into the coelomic cavity at the side of the dorsal mesentery, reaching from the

septum transversum cranially to the fifth lumbar segment caudally. The reproductive glands develop in the urogenital folds.

The mesonephric bodies are the permanent kidneys in fish and amphibians, but in reptiles, birds, and mammals, they atrophy and for the most part disappear synchronously with the development of the permanent kidneys. The atrophy begins during the sixth or seventh week and rapidly proceeds, so that by the beginning of the fourth month only the ducts and a few of the tubules remain.

#### METANEPHROS AND PERMANENT KIDNEY

The rudiments of the permanent kidneys make their appearance about the end of the first or the beginning of the second month.

Each kidney has a two-fold origin, part arising from the metanephros, and part as a diverticulum from the caudal end of the mesonephric duct, close to where the latter opens into the cloaca (Figs. 17-2; 17-3).

The metanephros arises in the intermediate cell mass caudal to the mesonephros, which it resembles in structure. The diverticulum from the mesonephric duct grows dorsalward and cranialward along the dorsal abdominal wall, where its blind extremity expands and subsequently divides into several buds that form the rudiments of the pelvis and calyces of the kidney; by continued growth and subdivision it gives rise to the collecting tubules of the kidney. The caudal portion of the diverticulum becomes the ureter. The secretory tubules are developed from the metanephros, which is

**Fig. 17-2.** Tail end of human embryo 25 to 29 days old. (From model by Keibel.)

molded over the growing end of the diverticulum from the mesonephric duct.

The tubules of the metanephros, unlike those of the pronephros and mesonephros, do not open into the mesonephric duct. One end expands to form a glomerulus, while the rest of the tubule rapidly elongates to form the convoluted and straight tubules, the loops of Henle,<sup>1</sup> and the connecting tubules; these last establish communication with the collecting tubules derived from the ultimate ramifications of the ureteric diverticulum. The mesoderm around the tubules condenses to form the connective tissue of the kidney. The ureter opens at first into the caudal end of the mesonephric duct; after the sixth week it is separated from the mesonephric duct and opens independently into the part of the cloaca that ultimately becomes the bladder (Figs. 17-2; 17-3).

The secretory tubules of the kidney be-

<sup>1</sup>Friedrich Gustav Jacob Henle (1809-1885): A German anatomist (Zurich, Heidelberg, and Göttingen).

**Fig. 17-3.** Tail end of human embryo 32 to 33 days old. (From model by Keibel.)

come arranged into pyramidal masses or lobules (Fig. 17-4). The lobulated condition of the kidneys exists for some time after birth, and traces of it may be found even in the adult. The kidney of the ox and many other animals remains lobulated throughout life.

## URINARY BLADDER

The bladder is formed partly from the endodermal cloaca and partly from the ends of the mesonephric ducts; the allantois has no share in its formation. After the rectum has separated from the dorsal part of the cloaca, the ventral part becomes subdivided into three portions: (1) an anterior **vesico-urethral portion** continuous with the allantois, into which the mesonephric ducts open; (2) an intermediate narrow channel, the **pelvic portion**; and (3) a posterior **phallic portion**, closed externally by the urogenital membrane. The second and third parts together constitute the **urogenital sinus** (Figs. 17-5; 17-6). The vesicourethral portion absorbs the ends of the mesonephric ducts and the associated ends of the renal diverticula, and these give rise to the trigone of the bladder and part of the prostatic urethra. The remainder of the vesicourethral portion forms the body of the bladder and part of the prostatic urethra; its apex is prolonged to the umbilicus as a narrow canal (the **urachus**), which later is obliterated and becomes the middle umbilical ligament.

**Fig. 17-4.** The kidneys and suprarenal glands of a newborn child. Anterior aspect.

FIG. 17-5. Urogenital sinus of female human embryo 8½ to 9 weeks old. (From model by Keibel.)

## Development of Generative Organs

### GENITAL GLANDS

The first appearance of the genital gland is essentially the same in the two sexes; it consists of a thickening of the epithelial layer that lines the peritoneal cavity on the medial side of the urogenital fold. The thick plate of epithelium pushes the mesoderm before it and forms a distinct projection, the **genital ridge** (Fig. 17-7). From it the testis in the male and the ovary in the female are developed. At first the mesonephros and genital ridge are suspended by a common mesentery, but as the embryo grows the genital ridge gradually becomes pinched off from the mesonephros, with which it is at first continuous, though it still remains connected to the remnant of this body by a fold of peritoneum,

FIG. 17-6. Tail end of male human embryo, from 8½ to 9 weeks old. (From model by Keibel.)

the **mesorchium** or **mesovarium**. About the seventh week the distinction of sex in the genital ridge begins to be perceptible.

### TESTIS

At first the testis is a collection of cells derived from the coelomic epithelium with a surface covering and a central mass. As sexual differentiation begins, a series of cords appears in the central mass (Fig. 17-8), surrounded by a concentration of cells that later is converted into the tunica albuginea. The tunica separates the cords from the surface epithelium, excluding it from any part in forming the parenchyma of the testis. The more peripheral parts of the cords develop into the seminiferous tubules; the central parts run together toward the future mediastinum testis, forming a network that becomes the rete testis.

FIG. 17-7. A, Diagrammatic cross section to show sites and migration of primordial germ cells from mesentery to gonad. B, Undifferentiated gonad. (Redrawn from Allan, F. D., *Essentials of Embryology*, Oxford University Press, 1960.)

**Fig. 17-8.** Differentiation of testis; A, B, and C represent progressively later stages. (Redrawn from Allan, F. D., *Essentials of Embryology*, Oxford University Press, 1960.)

### MALE MESONEPHRIC DUCT

In the male, the mesonephric duct (Wolffian duct) (see page 1515) persists and forms the epididymis, the ductus deferens, and the ejaculatory duct; the seminal vesicle arises during the third month as a lateral diverticulum from its caudal end (Fig. 17-9). A large part of the cranial portion of the mesonephros atrophies and disappears, but a few tubules may persist as the appendix of the epididymis; this vestigial structure ends blindly. From the remainder of the cranial tubules the efferent ducts of the testis form.

The caudal tubules are represented by the ductuli aberrantes and the paradidymis.

### DESCENT OF THE TESTES

At an early period of fetal life, the testes are placed at the dorsal part of the abdominal cavity; they are covered by the peritoneum and each is attached to the mesonephros by a peritoneal fold, the **mesorchium**.

From the ventral part of the mesonephros, a fold of peritoneum termed the **inguinal fold** grows ventralward to meet and fuse with the **inguinal crest**, a peritoneal fold that grows dorsalward from the anterolateral abdominal wall. The testis thus acquires an indirect connection with the anterior abdominal wall, and at the same time a portion of the peritoneal cavity lateral to these fused folds is marked off as the future **saccus vaginalis**.

In the inguinal crest a peculiar structure, the **gubernaculum testis**, makes its appearance. This is at first a slender band that extends from the part of the skin of the groin that afterward forms the scrotum through the inguinal canal to the body and epididy-

mis of the testis. As development advances, the peritoneum covering the gubernaculum forms two folds, one above the testis and the other below it. The fold cranial to the testis is the **plica vascularis**, which ultimately contains the testicular vessels; the caudal fold, the **plica gubernatrix**, contains the lower part of the gubernaculum, which has now grown into a thick cord. It ends caudally at the abdominal inguinal ring beside a tube of peritoneum, the **saccus** or **processus vaginalis**, which protrudes down the inguinal canal. By the fifth month the cranial part of the gubernaculum has disappeared, but the caudal part now consists of a central core of unstriated muscle fiber and an outer layer of striped elements connected with the abdominal wall. The main portion of the gubernaculum is attached to the skin at the point where the scrotum develops, and as the pouch forms, most of the caudal end of the gubernaculum is carried with it; other bands extend to the medial side of the thigh and to the perineum.

The tube of peritoneum constituting the **saccus** or **processus vaginalis** projects itself downward into the inguinal canal and emerges at the superficial inguinal ring, pushing before it a part of the obliquus internus and the fascia of the obliquus externus, which form respectively the cremaster muscle and the external spermatic fascia. It forms a gradually elongating sac that eventually reaches the bottom of the scrotum, and behind this sac the testis descends. Since the growth of the gubernaculum is not commensurate with the growth of the body of the fetus, the latter increasing more rapidly in relative length, it has been assumed that this prevents cranialward displacement of the testis. In addition, the gubernaculum may actually shorten, in which case it might

**FIG. 17-9.** Diagrammatic representation of the differentiation of the male genital ducts. A, Undifferentiated stage. B, Early differentiation. C, The condition just prior to birth when testis is undescended. Dash lines indicate position of testis after descent and dotted lines the position of the obliterated paramesonephric duct. Vestigial structures retained from the latter are labeled. (Redrawn from Allan, F. D., *Essentials of Embryology*, Oxford University Press, 1960.)

exert traction on the testis and tend to displace it toward the scrotum. By the end of the eighth month the testis has reached the scrotum, preceded by the processus vaginalis, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the saccus

vaginalis normally closes, and this obliteration extends gradually downward to within a short distance of the testis. The peritoneum surrounding the testis is then cut off entirely from the general peritoneal cavity and becomes the **tunica vaginalis** (Fig. 17-10).

Occasionally the testis fails to descend or

**FIG. 17-10.** Diagram illustrating descent of the testis: A, Before descent. The processus vaginalis is present before descent begins, the testis lying behind the peritoneum. B, Descent nearly complete but processus vaginalis not obliterated. C, Processus vaginalis obliterated except for the terminal portion, which persists as the tunica vaginalis of the adult.

the descent is incomplete, a condition known as **cryptorchidism**. In such cases administration of an extract of the pituitary gland may cause the testis to occupy its normal position. This would seem to indicate that the descent may to some extent be under hormonal control.

## PROSTATE

The prostate arises between the third and fourth months as a series of solid diverticula from the epithelium lining the urogenital sinus and vesicourethral part of the cloaca. These buds arise in five distinct groups, grow rapidly in length, and soon acquire a lumen. Eventually the prostatic urethra and ejaculatory ducts are embedded in a five-lobed gland, the parts of which are called the median, anterior, posterior, and lateral lobes. The lateral lobes are the largest. There are no distinct dividing lines between the parts of the formed gland, and the divisions are important only because of their individual peculiarities in disease processes.

**Skene's ducts**<sup>1</sup> in the female urethra are regarded as the homologues of the prostatic glands.

The **bulbourethral glands of Cowper**<sup>2</sup> in the male and the **greater vestibular glands of Bartholin**<sup>3</sup> in the female also arise as diverticula from the epithelial lining of the urogenital sinus.

## OVARY

The ovary (Fig. 17-11), formed from the genital ridge, is at first a collection of cells derived from the coelomic epithelium; later the mass is differentiated into a central part of medulla covered by a surface layer, the **germinal epithelium**. Between the cells of the germinal epithelium a number of larger cells, the **primitive ova**, are found. These are

<sup>1</sup>Alexander Johnston Chalmers Skene (1837-1900): An American gynecologist (New York).

<sup>2</sup>William Cowper (1666-1709): An English surgeon (London).

<sup>3</sup>Caspar Bartholin (1655-1738): A Danish anatomist (Copenhagen).

**FIG. 17-11.** Differentiation of ovary; A, B, and C represent progressively later stages. (Redrawn from Allan, F. D., *Essentials of Embryology*, Oxford University Press, 1960.)

carried into the subjacent stroma by bud-like ingrowths (**genital cords**) of the germinal epithelium. The surface epithelium ultimately forms the permanent epithelial covering of this organ; it soon loses its connection with the central mass and a tunica albuginea develops between them. The ova are derived chiefly from the cells of the central mass; these are separated from one another by the growth of connective tissue in an irregular manner. Each ovum acquires a covering of connective tissue (follicle) cells, and in this way the rudiments of the ovarian follicles are formed.

**Primordial germ cells** (Fig. 17-3) are, according to some authors, set aside at a very early age from the somatic cells. They are first recognized in the yolk sac. Later they migrate through the mesentery into the primitive germinal epithelium, to be carried into the gonad with the sex cords, and later still they develop either into ova in the female or sperm cells in the male. Some authors deny their existence while others claim they all degenerate and take no part in the formation of the adult sex cells.

#### FEMALE MESONEPHROS AND MESONEPHRIC DUCT

In the female, these structures atrophy (see page 1516). The remains of the mesonephric tubules may be divided into three groups. One group of tubules from the cranial portion of the mesonephros persists and produces one or more **vesicular appendices** in the fringes of the uterine tube. The middle and largest group, together with a segment of the mesonephric duct, persist as the **epoöphoron** (organ of Rosenmüller<sup>1</sup>). Persistent portions of the mesonephric duct are known as **Gartner's ducts**<sup>2</sup> (Fig. 17-55). These may exist as part of the epoöphoron or as isolated segments as far as the hymen. The third and most caudal group of remaining mesonephric ducts constitutes the **paroöphoron**, which usually disappears completely before the adult stage. Any one of these vestigial tubules that persists in the adult as a stalked vesicle is called an **hydatid**.

#### PARAMESONEPHRIC DUCTS

Shortly after the formation of the mesonephric ducts, the paramesonephric ducts (Müllerian ducts<sup>3</sup>) develop (Fig. 17-12). Each arises on the lateral aspect of the corresponding mesonephric duct as a tubular invagination of the cells lining the coelom (Fig. 17-12). The orifice of the invagination remains patent and undergoes enlargement and modification to form the abdominal ostium of the uterine tube. The ducts pass caudward lateral to the mesonephric ducts, but toward the caudal end of the embryo they cross to the medial side of these ducts, and thus come to lie side by side between and caudal to the latter—the four ducts forming what is termed the **genital cord**. The paramesonephric ducts end in an epithelial elevation, the **paramesonephric eminence**, on the ventral part of the cloaca between the orifices of the mesonephric ducts; at a later date they open into the cloaca in this situation.

In the male the paramesonephric (Müllerian) ducts atrophy, but traces of their cranial ends are represented by the **appendices testis** (hydatids of Morgagni<sup>4</sup>), while their caudal portions fuse to form the utriculus in the floor of the prostatic portion of the urethra.

In the female the paramesonephric (Müllerian) ducts persist and undergo further development. The portions that lie in the genital ridge fuse to form the uterus and vagina; the parts cranial to this ridge remain separate, and each forms the corresponding uterine tube—the abdominal ostium of which is developed from the cranial extremity of the original tubular invagination from the coelom. The fusion of the paramesonephric ducts begins in the third month, and the septum formed by their fused medial walls disappears. Entodermal epithelium of the urogenital sinus invades the region where the vagina forms, replacing the paramesonephric epithelium almost entirely, and for a time the vagina is represented by a solid rod of epithelial cells, but in fetuses of five months the lumen reappears. About the fifth month an annular constriction marks the position of the neck of the uterus, and

In the latter, the dotted lines indicate the position of the mesonephric duct and tubules. Vestigial structures derived from these are labeled. (Redrawn from Allan, F. D., *Essentials of Embryology*, Oxford University Press, 1960.)

after the sixth month the walls of the uterus begin to thicken. A ring-like outgrowth of epithelium occurs at the caudal end of the uterus and marks the future vaginal fornices. The hymen arises at the site of the paramesonephric eminence. It represents the separation between vagina and urogenital sinus.

#### DESCENT OF THE OVARIES

In the female there is also a gubernaculum, which effects a considerable change in the position of the ovary (Fig. 17-12), though not so extensive a change as that affecting the testis. The gubernaculum in the female lies

in contact with the fundus of the uterus and acquires adhesions to this organ; thus the ovary is prevented from descending below this level. The part of the gubernaculum between the ovary and the uterus ultimately becomes the proper **ligament of the ovary**, while the part between the uterus and the labium majus forms the **round ligament of the uterus**. A pouch of peritoneum analogous to the saccus vaginalis in the male accompanies the gubernaculum in the inguinal canal; this is called the **canal of Nuck**.<sup>1</sup>

In rare cases the gubernaculum may fail to develop adhesions to the uterus, and then the ovary descends through the inguinal canal into the labium majus. Under these circumstances its position resembles that of the testis.

#### EXTERNAL ORGANS OF GENERATION

As is shown in Figure 17-2, the cloacal membrane, composed of ectoderm and endoderm, initially extends from the umbilicus to the tail bud. The growing mesoderm extends to the midventral line for some distance caudal to the umbilicus and forms the lower part of the abdominal wall; it ends caudally in a prominent swelling, the **genital tubercle** (Fig. 17-13). Dorsal to this tubercle the urogenital part of the cloacal membrane separates the ingrowing sheets of mesoderm.

The first rudiment of the penis (or clitoris) is a structure termed the **phallus**; it is derived from the phallic portion of the cloaca which has extended on the end and sides of the undersurface of the genital tubercle. The terminal part of the phallus, representing the future glans, becomes solid; the remainder, which is hollow, is converted into a longitudinal groove by the absorption of the urogenital membrane.

*In the female* a deep groove forms around the phallus and separates it from the rest of the genital tubercle. The tissue at the sides of the genital tubercle grows caudalward as the **genital swellings**, which ultimately form the labia majora; the tubercle itself becomes the mons pubis. The labia minora arise by the continued growth of the lips of the groove on the undersurface of the phallus; the remainder of the phallus forms the clitoris.

*In the male* the early changes are similar, but the pelvic portion of the cloaca under-

goes much greater development, pushing before it the phallic portion. The genital swellings extend around between the pelvic portion and the anus, and form a scrotal area; during the changes associated with the descent of the testes this area is drawn out to form the scrotal sacs. The penis is developed from the phallus. As in the female, the urogenital membrane undergoes absorption, forming a channel on the undersurface of the phallus; this channel extends only as far forward as the corona glandis.

The **corpora cavernosa** of the penis (or clitoris) and of the urethra arise from the mesodermal tissue in the phallus. They are dense structures at first, but later vascular spaces appear in them and they gradually become cavernous.

The **prepuce** in both sexes is formed by the growth of a solid plate of ectoderm into the superficial part of the phallus; on coronal section this plate presents the shape of a horseshoe. By the breaking down of its more centrally situated cells, the plate is split into two lamellae, and a cutaneous fold, the prepuce, is liberated and forms a hood over the glans. Adherent prepuce is not a secondary adhesion but a hindered central desquamation.

#### URETHRA

As already described, in both sexes the phallic portion of the cloaca extends to the undersurface of the genital tubercle as far forward as the apex. At the apex the walls of the phallic portion come together and fuse, the lumen is obliterated, and a solid plate, the **urethral plate**, is formed. The remainder of the phallic portion is tubular for a time, and then, by the absorption of the urogenital membrane, it establishes a communication with the exterior; this opening is the **primitive urogenital ostium**, which extends forward to the corona glandis.

*In the female* this condition is largely retained; the portion of the groove on the clitoris broadens out while the body of the clitoris enlarges, and thus the adult urethral opening is situated behind the base of the clitoris.

*In the male*, by the greater growth of the pelvic portion of the cloaca, a longer urethra is formed, and the primitive ostium is carried distalward with the phallus, but it still ends at the corona glandis. Later it closes

<sup>1</sup>Anton Nuck (1650-1692): A Dutch anatomist (Leiden).

**Fig. 17-13.** Stages in the development of the external sexual organs in the male (A, C, and E) and female (B, D, and F). (Drawn from the Ecker-Ziegler models.)

from proximally to distally. Meanwhile the urethral plate of the glans breaks down centrally to form a median groove continuous with the primitive ostium. This groove also closes proximally, so that the external urethral opening is shifted distalward to the end of the glans (Fig. 17-6).

## Urinary Organs

The urinary organs comprise the **kidneys**, which produce the urine; the **ureters**, or ducts, which convey urine to the **urinary**

**bladder**, where it is retained for a time; and the **urethra**, through which it is discharged from the body.

## KIDNEYS

The **kidneys** (renes) are situated in the dorsal part of the abdomen, one on either side of the vertebral column, covered by the peritoneum and surrounded by a mass of fat and loose areolar tissue. Their cranial extremities are on a level with the cranial border of the twelfth thoracic vertebra, their

caudal extremities on a level with the third lumbar. The right kidney is usually slightly more caudal than the left, probably due to the presence of the liver. The long axis of each kidney is parallel with the vertebral column. Each kidney is about 11.25 cm long, 5 to 7.5 cm wide, and rather more than 2.5 cm thick. The left is somewhat longer and narrower than the right. In the adult male, the kidney weighs 125 to 170 gm; in the adult

female, 115 to 155 gm. The combined weight of the two kidneys in proportion to that of the body is about 1 to 240. The kidneys in the newborn are about three times as large in proportion to the body weight as in the adult. The kidney has a characteristic form similar to a bean, and presents for examination two surfaces, two borders, and a cranial and caudal extremity (Fig. 17-14).

**FIG. 17-14.** The right kidney and suprarenal gland. A, Suprarenal gland. B, Kidney, surface view. C, Kidney, longitudinal section showing pelvis. (Eycleshymer and Jones.)

## Surfaces

The **ventral surface** (Fig. 17-15) of each kidney is convex and faces ventralward and slightly lateralward. Its relations to adjacent viscera differ so completely on the two sides that separate descriptions are necessary.

**VENTRAL SURFACE OF RIGHT KIDNEY.** A narrow portion at the cranial extremity is in relation with the right suprarenal gland (Fig. 17-17). A large area just caudal to this and involving about three-fourths of the surface lies in the renal impression on the visceral surface of the liver, and a narrow but somewhat variable area near the medial border is in contact with the descending part of the duodenum. The caudal part of the ventral surface is in contact laterally with the right colic flexure, and medially, as a rule, with the small intestine. The areas in relation

with the liver and small intestine are covered by peritoneum; the suprarenal, duodenal, and colic areas are devoid of peritoneum.

**VENTRAL SURFACE OF LEFT KIDNEY.** A small area along the cranial part of the medial border is in relation with the left suprarenal gland, and close to the lateral border is a long strip in contact with the renal impression on the spleen (Fig. 17-17). A somewhat quadrilateral field, about the middle of the ventral surface, marks the site of contact with the body of the pancreas, on the deep surface of which are the lienal vessels. Above this is a small triangular portion, between the suprarenal and splenic areas, in contact with the posterior surface of the stomach. Caudal to the pancreatic area, the lateral part is in relation with the left colic flexure, the medial part, with the small intes-

**Fig. 17-15.** Ventral view of abdominal viscera after removal of the peritoneum of the dorsal abdominal wall, showing kidneys, suprarenal glands, and great vessels. (Corning.)

tine. The areas in contact with the stomach and spleen are covered by the peritoneum of the omental bursa, while that in relation to the small intestine is covered by the peritoneum of the greater sac; dorsal to the latter are some branches of the left colic vessels. The suprarenal, pancreatic, and colic areas are devoid of peritoneum.

**DORSAL SURFACE.** The dorsal surface (Figs. 17-16; 17-18) of each kidney is directed dorsalward and medialward. It is embedded in areolar and fatty tissue and entirely devoid of peritoneal covering. It lies upon the diaphragm; the medial and lateral lumbocostal arches; the psoas major, the quadratus

lumborum, and the tendon of the transversus abdominis muscles; the subcostal and one or two of the upper lumbar arteries; and the last thoracic, iliohypogastric, and ilioinguinal nerves. The cranial extremity of the right kidney rests upon the twelfth rib; the left, usually on the eleventh and twelfth ribs. The diaphragm separates the kidney from the pleura, which dips down to form the phrenicocostal sinus, but frequently the muscular fibers of the diaphragm are defective or absent over a triangular area immediately above the lateral lumbocostal arch, in which case the perinephric areolar tissue is in contact with the diaphragmatic pleura.

**FIG. 17-16.** Dissection of abdominal viscera, dorsal view showing relation of the kidneys. (After Corning's *Topographischen Anatomie* in Eycleshymer and Jones.)

FIG. 17-17. The ventral surfaces of the kidneys, showing the areas of contact of neighboring viscera.

### Borders

The **lateral border** (*external border*) is convex and directed toward the posterolateral wall of the abdomen. On the left side it is in contact, at its cranial part, with the spleen.

The **medial border** (*internal border*) is concave in the center and convex toward

either extremity; it is directed ventralward and a little caudalward. Its central part has a deep longitudinal fissure, bounded by prominent overhanging ventral and dorsal lips. This fissure, named the **hilum**, transmits the vessels, nerves, and ureter. Above the hilum the medial border is in relation with the suprarenal gland; below the hilum, with the ureter.

FIG. 17-18. The dorsal surfaces of the kidneys, showing areas of relation to the parietes.

**FIG. 17-19.** Visceral and parietal peritoneum associated with large intestine. Small intestine and mesentery removed. (Tobin, 1944.)

The relative positions of the main structures in the hilum are as follows: the vein is ventral, the artery is in the middle, and the ureter is dorsal and directed caudalward. Frequently, however, branches of both artery and vein are placed dorsal to the ureter.

### Extremities

The **cranial extremity** (*extremitas superior*) is thick and round and is nearer the median line than the caudal extremity. It is surmounted by the suprarenal gland, which also covers a small portion of the ventral surface.

The **caudal extremity** (*extremitas inferior*) is smaller and thinner than the superior and farther from the median line. It extends to within 5 cm of the iliac crest.

### Renal Fascia

The kidney and its vessels are embedded in a mass of fatty tissue, termed the adipose capsule or *perirenal fat*, which is thickest at the margins of the kidney and is prolonged through the hilum into the renal sinus. The kidney and the adipose capsule together are

enclosed in a specialized lamination of the subserous fascia called the renal fascia (Figs. 17-19 to 17-22). It occupies a position between the internal investing layer of deep fascia (*transversalis, endoabdominal fascia*) and the stratum of subserous fascia associated with the intestine and its blood vessels (Fig. 17-20). In forming the renal fascia, the subserous fascia of the lateral abdominal wall splits into two fibrous lamellae near the lateral border of the kidney (Fig. 17-22). Both lamellae extend medially, the ventral one over the ventral surface of the kidney, the dorsal one over the dorsal surface. The anterior lamella continues over the renal vessels and aorta to join the similar membrane of the other side. The posterior lamella also continues across the midline but lies deep to the aorta, and there it is more adherent to the underlying deep fascia than in the region of the kidney. The renal fascia is connected to the fibrous tunic of the kidney by numerous trabeculae that traverse the adipose capsule and are strongest near the lower end of the organ. Dorsal to the fascia renalis is a large quantity of fat, which constitutes the *paranephric body (pararenal fat)*.

**FIG. 17-20.** Peritoneum associated with ascending colon dissected free and displaced to expose the deeper stratum of subserous fascia associated with kidney and great vessels. (Tobin, 1944.)

**FIG. 17-21.** Deeper stratum of subserous fascia dissected free and displaced to expose the transversalis fascia. (Tobin, 1944.)

### Fixation of the Kidney

The kidneys are not rigidly fixed to the abdominal wall, and since they are in contact with the diaphragm, they move with it during respiration. They are held in position by the renal fascia just described and by the large renal arteries and veins. That the adipose capsule and the paranephric fat body

play an important part in holding the kidney in position is indicated by the occurrence of a condition called movable kidney in emaciated individuals.

### General Structure of the Kidney

The kidney is invested by a fibrous tunic or capsule that forms a firm, smooth covering to the organ. The tunic can be stripped off easily, but in doing so numerous fine processes of connective tissue and small blood vessels are torn. When the capsule is stripped off, the surface of the kidney is smooth and deep red. In infants, fissures extending for some depth may be seen on the surface of the organ, a remnant of the lobular constriction of the gland.

If a vertical section of the kidney were made from its convex to its concave border, it would be seen that the hilum expands into a central cavity, the **renal sinus**; this contains the cranial part of the renal pelvis and the calyces, surrounded by some fat in which the branches of the renal vessels and nerves are embedded. The renal sinus is lined by a prolongation of the fibrous tunic, which is continuous with the covering of the pelvis of the kidney around the lips of the hilum.

The **minor renal calyces**, numbering 4 to 13, are cup-shaped tubes, each of which embraces usually one but occasionally two or more of the renal papillae. They unite to form two or three short tubes, the major calyces, and these in turn join to form a

**FIG. 17-22.** Transverse section, showing relations of renal fascia. (Tobin, 1944.)

funnel-shaped sac, the **renal pelvis**. Spirally arranged muscles surrounding the calyces may have a milking action on these tubes, thereby aiding the flow of urine into the renal pelvis. As the pelvis leaves the renal sinus, it diminishes rapidly in caliber and merges insensibly into the **ureter**, the excretory duct of the kidney.

The kidney is composed of an internal **medullary** and an external **cortical substance** (Fig. 17-23).

The **medullary substance** consists of a series of striated conical masses, termed the **renal pyramids**, of which there are 8 to 18. Their bases are directed toward the circumference of the kidney, while their apices converge toward the renal sinus, where they form prominent papillae projecting into the lumen of the minor calyces.

The **cortical substance** is reddish brown and soft and granular. It lies immediately beneath the fibrous tunic, arches over the bases of the pyramids, and dips in between adjacent pyramids toward the renal sinus.

The parts dipping between the pyramids are named **renal columns** (of Bertini<sup>1</sup>), while the portions that connect the renal columns to each other and intervene between the bases of the pyramids and the fibrous tunic are called the **cortical arches**. If the cortex is examined with a lens, it is seen to consist of a series of lighter colored, conical areas, termed the *radiate part*, and a darker colored intervening substance, which from the complexity of its structure is named the *convoluted part*. The rays gradually taper toward the circumference of the kidney and consist of a series of outward prolongations from the base of each renal pyramid.

### Microscopic Anatomy

The **renal tubules** (Fig. 17-23), of which the kidney is for the most part composed, commence in the cortical substance. After

<sup>1</sup>Exupère Joseph Bertin (1712–1781): A French anatomist (Rheims).

Longitudinal section through the kidney near the hilum showing the renal cortex and medulla and the blood vessels.

pursuing a circuitous course through the cortical and medullary substances, they finally end at the apices of the renal pyramids by open mouths, so that the fluid they contain is emptied through the calyces into the pelvis of the kidney. If the surface of one of the papillae is examined with a lens, it is seen to be studded over with 16 to 20 minute openings, the orifices of the renal tubules. Pressure applied to a fresh kidney will cause urine to exude from these orifices.

The tubules commence in the cortex and renal columns as the **renal corpuscles** or **Malpighian<sup>1</sup> bodies**. They are small, round, deep red masses, varying in size but averaging about 0.2 mm in diameter. Each of these bodies is composed of two parts: a central **glomerulus** of vessels, and a double-walled membranous envelope, the **glomerular capsule** (capsule of Bowman<sup>2</sup>), which is the invaginated pouch-like commencement of a renal tubule.

**GLOMERULUS.** The glomerulus is a tuft of nonanastomosing capillaries, among which there is a scanty amount of connective tissue. This capillary tuft is derived from an arteriole, the *afferent vessel*, which enters the capsule, generally at a point opposite to that at which the capsule joins the tubule (Fig. 17-24). Upon entering the capsule, the afferent arteriole divides into 2 to 10 primary branches, which in turn subdivide into about 50 capillary loops that generally do not anastomose. These loops are 300 to 500  $\mu\text{m}$  long. The capillaries join to form the *efferent arteriole*, which leaves Bowman's capsule adjacent to the afferent vessel, the latter generally being the larger of the two. The total surface area of the capillaries of all glomeruli is about 1 square meter.

For a variable distance before the afferent arteriole enters the glomerulus, the muscle cells of the media adjacent to the distal convolution of its own nephron are modified, appearing as relatively large afibrillar cells. This structure presents evidence of glandular activity. At times it appears partially to invest the artery in a nest-like group of cells embedded in a delicate fibrillar network and is known as the **juxtaglomerular apparatus**.

**GLOMERULAR CAPSULE.** The **glomerular** or **Bowman's capsule**, which surrounds the glo-

merulus, consists of a double-walled sac. The outer wall (parietal layer) is continuous with the inner wall (visceral layer) at the points of entrance and exit of the afferent and efferent vessels respectively. The cavity between the two layers is continuous with the lumen of the proximal convoluted tubule. The parietal layer is smooth. The visceral layer covers the glomerulus and dips in between the capillary loops, almost completely surrounding each one. Both layers of the capsule consist of flat epithelial cells that have a basement membrane. This covers the outer surface of the parietal layer and is continuous with that of the tubule cells. The basement membrane of the visceral layer is in contact with the glomerular capillaries. Microdissection experiments of living glomeruli show that they lie in a gelatinous matrix. The walls of the capillaries, the overlying cells of the visceral layer of the capsule, and the gelatinous matrix constitute a filter mechanism through which nonprotein constituents of the blood plasma can enter the tubule.

**RENAL TUBULE.** A renal tubule, beginning with the capsule of Bowman as it surrounds the glomerulus and ending where the tubule joins the excretory duct or collecting tubule, constitutes a **nephron**—the structural and functional unit of the kidney. There are about 1,250,000 of these units in each kidney.

During its course, a tubule has many changes in shape and direction. It is contained partly in the cortical and partly in the medullary substance. At its junction with the glomerular capsule, it exhibits a somewhat constricted portion, which is termed the **neck**. Beyond this the tubule becomes convoluted, and pursues a long course in the cortical substance constituting the **proximal convoluted tube**. The convolutions disappear as the tube approaches the medullary substance in a more or less spiral manner. Throughout this portion of its course the renal tubule is contained entirely in the cortical substance and has a fairly uniform caliber. It now enters the medullary substance, suddenly becomes much smaller, quite straight, and dips down for a variable depth into the pyramid, constituting the thin or **descending limb of Henle's loop**. Bending on itself, it forms what is termed the **loop of Henle** and ascending, it becomes suddenly enlarged, forming the thick or **ascending limb of Henle's loop**, which enters the cortical substance where it again becomes dila-

**FIG. 17-24.** Diagram of a portion of kidney lobule illustrating a nephron, typical histologic sections of the various divisions of a nephron, and the disposition of the renal vessels. The section of the collecting tubule is reproduced at a lower magnification than the divisions of the nephron. (Courtesy of R. G. Williams.)

ted and tortuous. It is now called the **distal convoluted tubule**. The terminal part of the ascending limb of Henle's loop crosses in contact with, or sometimes lies parallel to, the afferent arteriole of its own glomerulus. The turns of the distal convoluted tubule into which it merges lie among the coils of the proximal portion of the nephron and terminate in a narrow part that enters a collecting tubule.

The **straight or collecting tubes** commence in the radiate part of the cortex, where they receive the curved ends of the distal convoluted tubules. They unite at short intervals with one another, the resulting tubes presenting a considerable increase in caliber, so that a series of comparatively large tubes passes from the bases of the rays into the renal pyramids. In the medulla the tubes of each pyramid converge to join a central tube (duct of Bellini<sup>1</sup>), which finally opens on the summit of one of the papillae; the contents of the tube are therefore discharged into one of the minor calyces.

**Structure of the Renal Tubules.** The various parts of the nephron present quite different cellular appearances and these appearances vary depending upon the functional state of the cells. The **proximal convoluted tubule** is about 14 mm long and 59  $\mu$ m in diameter. It is composed of one layer of large cuboidal cells with central spherical nuclei. The cells dovetail laterally with one another and the lateral cell limits are rarely seen. The distal ends of the cells bulge into the lumen and are covered with a brush border. The cytoplasm is abundant and coarsely granular. Parallel striations in the cytoplasm perpendicular to the basement membrane are due to mitochondria.

The transition between the epithelium of the proximal convoluted tubule and the thin segment is abrupt. The **thin segment** may be absent in nephrons beginning near the surface of the kidney. It is composed of squamous cells with pale-staining cytoplasm and flat nuclei. The epithelial change from the descending limb to the **ascending or thick limb** is also quite abrupt. The cells become cuboidal and deeper-staining, with perpendicular striations in the basal parts but without distinct cell boundaries or brush borders.

At about the junction of the ascending limb with the distal convoluted tubule, the

nephron comes into contact with the juxtaglomerular cells of its own afferent arteriole. Here the epithelium of the tubule is greatly modified, having high cells and crowded nuclei. This constitutes the **macula densa** or epithelial plaque.

Transition to the tortuous **distal convoluted tubule** is gradual. This segment of the nephron is about 5 mm long and 35  $\mu$ m in diameter. The cells are lower and the lumen larger than in the proximal tubule. They do not have a brush border and the boundaries are fairly distinct. The distal convoluted tubule merges into a short connecting segment that joins the collecting or excretory tubule.

The collecting tubules have a typical epithelium which is quite different from that in the various portions of the nephron. In the smallest tubes, the cells are cuboidal and distinctly outlined with round nuclei and clear cytoplasm. As the tubules become larger, the cells are higher, finally becoming tall columnar cells in the ducts of Bellini. The columnar epithelium becomes continuous with the cells covering the surface of the papillae.

The length of the nephron varies from 30 to 38 mm, while the length of the collecting tubules is estimated at 20 to 22 mm.

**RENAL BLOOD VESSELS.** The kidney is plentifully supplied with blood by the renal artery, a large branch of the abdominal aorta (Fig. 17-24). Before entering the kidney substance the number and disposition of the branches of the renal artery exhibit great variation. In most cases, the renal artery divides into two primary branches, a larger anterior and a smaller posterior branch. The anterior branch supplies exclusively the anterior or ventral half of the organ and the posterior supplies the posterior or dorsal half. Therefore, there is a line (Brödel's line<sup>2</sup>) in the long axis of the lateral border of the kidney that passes between the two main arterial divisions in which there are no large vessels, a feature that is utilized to minimize hemorrhage when nephrotomy is done. The primary branches subdivide and diverge until they come to lie on the anterior and posterior aspects, respectively, of the calyces. Further subdivisions occur that enter the kidney substance and run between the pyramids. These are known as **interlobar arteries**. When these vessels reach the corticomedullary zone, they make more or less well-defined arches over the bases of the pyramids and are then called **arcuate arteries**. These vessels give off a series of branches called **interlobular arteries**.

<sup>1</sup>Lorenzo Bellini (1643-1704): An Italian anatomist (Pisa).

<sup>2</sup>Max Brödel (1870-1941): An American physician and medical artist (Baltimore).

The interlobular arteries and the terminal parts of the arcuate vessels run vertically and nearly parallel toward the cortex and periphery of the kidney. The interlobular arteries may terminate: (1) as an afferent glomerular artery to one or more glomeruli; (2) in a capillary plexus around the convoluted tubules in the cortices without relation to the glomerulus, therefore a nutrient artery; and (3) as a perforating capsular vessel. Divisions classified under (2) must be regarded as exceptional.

The most important and numerous branches of the interlobular arteries are the **afferent glomerular vessels**. These break up into capillary loops, the glomerulus, within Bowman's capsule. The loops unite to form the efferent arteriole. The **efferent glomerular vessel** forms a plexus about the convoluted tubule and part of Henle's loop and sends one or more branches toward the pelvis, the **arteria recta**, which supplies the collecting tubules and loops of Henle.

The arteriae rectae are derived chiefly from the efferent arterioles of glomeruli located in the boundary zone. They are frequently known as **arteriae rectae spuriae** to distinguish them from a few straight vessels arising directly from the arcuate or interlobular arteries without relation to glomeruli and hence called **arteriae rectae verae**. It is likely that the so-called arteriae rectae verae were once derived from an efferent glomerular vessel but that the glomerulus atrophied, thus giving them the appearance of true nutrient branches from the arcuate or interlobular arteries. No arteriae rectae are derived from the vessels of the cortical zone. It has not been determined whether anastomoses occur between the capillaries of adjacent nephrons. However, there is free anastomosis between the branches of the arteriae rectae. The arteriae rectae, or straight arteries, surround the limbs of Henle and pass down between the straight collecting tubules, where they form terminal plexuses around the tubes.

This plexus drains into the **venae rectae**, which in turn carry the blood to the interlobular veins, thence into the arcuate veins, then into the interlobar veins and finally into the renal veins, which discharge into the inferior vena cava. Note that the chief renal arteries have counterparts in the venous system. All veins from the dorsal half of the kidney cross to the ventral half between the minor calyces to join the ventral collecting veins before leaving the kidney. Whatever arterial anastomoses there are within the kidney occur beyond the glomeruli; the renal arteries and their branches, therefore, are terminal as far as the arteriae rectae. An exception to this condition is found in cases in which arteriovenous anastomoses have been described. These connections have been found in three locations: between the arteries and veins of the sinus renalis, between the subcapsular vessels, and between the interlobular arteries and veins. In the latter position particularly, arterial blood could reach the tubules of the nephron by retrograde flow through the veins. The constancy with which this type of anastomosis occurs or its rôle in the circulation of the kidney has not been accu-

ately determined. Anastomosis between veins is rich. The perforating capsular vessels, the terminations of interlobular arteries, form connections with nonrenal vessels in the fat that surrounds the kidney. They frequently drain into the subcapsular or **stellate veins**, which in turn drain into the interlobular veins.

The **lymphatics** of the kidney are described in Chapter 10.

**NERVES.** The nerves of the kidney, although small, number about 15. They have small ganglia and are derived from the renal plexus, which is formed by branches from the celiac plexus, the lower and outer part of the celiac ganglion and aortic plexus, and from the lesser and lowest splanchnic nerves. They communicate with the testicular plexus, a circumstance that may explain the occurrence of pain in the testis in disorders of the kidney. They accompany the renal artery and its branches and are distributed to the blood vessels and to the cells of the urinary tubules.

**CONNECTIVE TISSUES.** Although the tubules and vessels are closely packed, a small amount of connective tissue (*intertubular stroma*), continuous with the fibrous tunic, binds them firmly together and supports the blood vessels, lymphatics, and nerves.

**VARIATIONS.** Malformations of the kidney are common. One kidney may be absent entirely, but the number of these cases is small. One kidney may be congenitally atrophied, in which case the kidney is very small but usually healthy in structure. These cases are important and must be taken into account when nephrectomy is contemplated. A more common malformation is the fusion of the two kidneys together. They may be joined together only at their lower ends by means of a thick mass of renal tissue, forming a horseshoe-shaped body, or they may be completely united, forming a disc-like kidney, from which two ureters descend into the bladder. These fused kidneys are generally situated in the midline of the abdomen, but may be displaced as well. In some mammals, e.g., ox and bear, the kidney consists of a number of distinct lobules; this lobulated condition is characteristic of the kidney of the human fetus, and traces of it may persist in the adult. Sometimes the pelvis is duplicated, while a double ureter is not uncommon. In some rare instances a third kidney may be present.

One or both kidneys may be misplaced as a congenital condition and remain fixed in this abnormal position. They are then often misshapen. They may be situated higher, though this is uncommon, or lower than normal, or removed farther from the vertebral column than usual. They may be displaced into the iliac fossa, over the sacroiliac joint, onto the promontory of the sacrum, or into the pelvis between the rectum and bladder or by the side of the uterus. In these latter cases they may cause serious trouble.

The kidney may also be displaced as a congenital condition but not fixed; it is then known as a *floating kidney*. This disorder is believed to be due to the fact

that the kidney is completely enveloped by peritoneum, which then passes backward to the vertebral column as a double layer, forming a mesonephron that permits movement. The kidney may also be misplaced as an acquired condition; in these cases the kidney is mobile in the tissues that surround it, moving with the capsule in the perinephric tissues. This condition is known as *movable kidney*, and is more common in females than in males. It occurs in badly nourished people or in those who have become emaciated from any cause. It must not be confused with the *floating kidney*, which is a congenital condition due to the development of a mesonephron. The two conditions cannot, however, be distinguished until the abdomen is opened or the kidney explored from the loin. Accessory renal arteries that enter one or both poles of the kidney instead of at the hilum are fairly common.

### URETERS

The **ureters** (Figs. 17-15; 17-16) are the two tubes that convey the urine from the kidneys to the urinary bladder. The renal portion of each tube commences within the sinus of the

corresponding kidney as a number of short cup-shaped tubes, termed **calyces**, which encircle the renal papillae (Fig. 17-25). Since a single calyx may enclose more than one papilla, the calyces are generally fewer in number than the pyramids—the former varying from 7 to 13, the latter from 8 to 18. The calyces join to form two or three short tubes, and these unite to form a funnel-shaped dilatation named the **renal pelvis**. The pelvis is situated partly inside and partly outside the renal sinus, where it becomes continuous with the ureter, usually on a level with the spinous process of the first lumbar vertebra.

The **ureter proper** varies in length from 28 to 34 cm, the right being about 1 cm shorter than the left. It is a thick-walled narrow tube, not of uniform caliber, varying from 1 mm to 1 cm in diameter. It runs caudalward and medialward on the psoas major muscle, and entering the pelvic cavity, finally opens into the fundus of the bladder.

**Fig. 17-25.** Ureters, pelves, and minor calyces after intravenous injection of a radiopaque medium (Uroselectan). Note cupping of minor calyces; the relation of the ureter to the transverse processes of the lumbar vertebrae, and the psoas major. The arrow points to the shadow of the right kidney. Anterior view.

### Abdominal Part

The abdominal part lies behind the peritoneum on the medial part of the psoas major embedded in the subserous fascia, and is crossed obliquely by the testicular vessels. It enters the pelvic cavity by crossing either the termination of the common iliac vessels or the commencement of the external iliac vessels (Fig. 17-15).

At its origin, the right ureter is usually covered by the descending part of the duodenum. In its course, it lies to the right of the inferior vena cava, and is crossed by the right colic and ileocolic vessels, while near the superior aperture of the pelvis, it passes dorsal to the caudal part of the mesentery and the terminal part of the ileum. The left ureter is crossed by the left colic vessels, and near the superior aperture of the pelvis, it passes behind the sigmoid colon and its mesentery.

### Pelvic Part

This part runs at first caudalward on the lateral wall of the pelvic cavity, along the anterior border of the greater sciatic notch and under cover of the peritoneum. It lies ventral to the internal iliac artery medial to the obturator nerve and the obturator, inferior vesical, and middle rectal arteries. Opposite the lower part of the greater sciatic foramen it inclines medialward and reaches the lateral angle of the bladder, where it is situated ventral to the upper end of the seminal vesicle; here the ductus deferens crosses to its medial side, and the vesical veins surround it. Finally, the ureters run obliquely for about 2 cm through the wall of the bladder and open by slit-like apertures into the cavity of the viscus at the lateral angles of the trigone. When the bladder is distended, the openings of the ureters are about 5 cm apart, but when it is empty and contracted, the distance between them is diminished by one-half. Owing to their oblique course through the coats of the bladder, the upper and lower walls of the terminal portions of the ureters become closely applied to each other when the viscus is distended, and acting as valves, prevent regurgitation of urine from the bladder. The ureter normally undergoes constriction at three points in its course: (1) at the ureteropelvic junction (average diameter, 2 mm); (2) where it crosses

the iliac vessels (average diameter, 4 mm); (3) where it joins the bladder (average diameter, 1 to 5 mm). Between these points the abdominal ureter averages 10 mm in diameter, and the pelvic ureter, 5 mm.

In the **female**, the ureter forms, as it lies in relation to the wall of the pelvis, the posterior boundary of a shallow depression named the **ovarian fossa**, in which the ovary is situated. It then runs medialward and ventralward on the lateral aspect of the cervix uteri and upper part of the vagina to reach the fundus of the bladder. In this part of its course it is accompanied for about 2.5 cm by the uterine artery, which then crosses over the ureter and ascends between the two layers of the broad ligament. The ureter is about 2 cm distant from the side of the uterine cervix.

### Structure

The ureter is composed of three coats: **fibrous**, **muscular**, and **mucous** (Fig. 17-26).

The **fibrous coat** is continuous at one end with the fibrous tunic of the kidney on the floor of the sinus, while at the other it is lost in the fibrous structure of the bladder.

In the renal pelvis the **muscular coat** consists of two layers, longitudinal and circular: the longitudinal fibers become lost upon the sides of the papillae at the extremities of the calyces; the circular fibers may be traced

FIG. 17-26. Transverse section of ureter.

surrounding the medullary substance in the same situation. In the ureter proper the muscular fibers are distinct and arranged in three layers: an external longitudinal layer, a middle circular layer, and an internal layer, which is less distinct than the other two, but has a general longitudinal direction. This internal layer is found only in the neighborhood of the bladder.

The **mucous coat** is smooth, having only a few longitudinal folds that become effaced by distention. It is continuous with the mucous membrane of the bladder below, while it is prolonged over the papillae of the kidney above. Its epithelium is transitional and resembles that found in the bladder (see Fig. 17-33). It consists of several layers of cells, of which the innermost—that is to say, the cells in contact with the urine—are somewhat flattened, with concavities on their deep surfaces into which the rounded ends of the cells of the second layer fit. These intermediate cells more or less resemble columnar epithelium; they are pear-shaped, with rounded internal extremities that fit into the concavities of the cells of the first layer, and narrow external extremities that are wedged between the cells of the third layer. The external or third layer consists of conical or oval cells that vary in number in different parts and have processes that extend into the basement membrane. Beneath the epithelium and separating it from the muscular coats is a dense layer of fibrous tissue containing many elastic fibers.

**VESSELS AND NERVES.** The **arteries** supplying the ureter are branches from the renal, testicular, internal iliac, and inferior vesical arteries.

The **nerves** are derived from the inferior mesenteric, testicular, and pelvic plexuses. The lower one-third of the ureter contains nerve cells that are probably incorporated in vagus efferent chains. The afferent supply of the ureter is contained in the eleventh and twelfth thoracic and first lumbar nerves. The vagus supply to the ureter probably also has afferent components.

**VARIATIONS.** The upper portion of the ureter is sometimes double; rarely it is double the greater part of its extent, or even completely so. In such cases there are two openings into the bladder. Asymmetry in these variations is common.

## URINARY BLADDER

The **urinary bladder** (Fig. 17-27) is a musculomembranous sac that acts as a reservoir for the urine. As its size, position, and rela-

tions vary according to the amount of fluid it contains, it is necessary to study it as it appears (a) when empty, and (b) when distended (Fig. 17-28). In both conditions, the position of the bladder varies with the condition of the rectum, being pushed upward and forward when the rectum is distended.

### Empty Bladder

When hardened in situ, the empty bladder has the form of a flattened tetrahedron, with its vertex tilted ventralward. It has a fundus, a vertex, a superior and an inferior surface. The **fundus** (Fig. 17-44) is triangular and is directed caudalward and dorsalward toward the rectum, from which it is separated by the rectovesical fascia, the seminal vesicles, and the terminal portions of the ductus deferentes. The **vertex** is directed ventralward toward the upper part of the symphysis pubis, and from it the median umbilical ligament is continued cranialward on the anterior abdominal wall to the umbilicus. The peritoneum covering the ligament is the median umbilical fold.

The **superior surface** is triangular, bounded on either side by a lateral border that separates it from the inferior surface, and by a posterior border, represented by a line joining the two ureters, which intervenes between it and the fundus. The lateral borders extend from the ureters to the vertex, and from them the peritoneum is carried to the walls of the pelvis. On either side of the bladder the peritoneum shows a depression, named the **paravesical fossa**. The superior surface is covered by peritoneum and is in relation with the sigmoid colon and some of the coils of the small intestine. When the bladder is empty and firmly contracted, this surface is convex and the lateral and posterior borders are round, whereas if the bladder is relaxed it is concave, and the interior of the viscus, as seen in a median sagittal section, has the appearance of a V-shaped slit, with a shorter posterior and a longer anterior limb—the apex of the V corresponding with the internal orifice of the urethra.

The **inferior surface** is uncovered by peritoneum. It may be divided into a posterior or prostatic area and two lateral surfaces. The prostatic area rests upon and is in direct continuity with the base of the prostate; and from it the urethra emerges. The lateral portion of the inferior surface is directed cau-

**Fig. 17-27.** Median sagittal section through male pelvis, viewed from left side. (Eycleshymer and Jones.)

dalward and lateralward and is separated from the symphysis pubis by the prevesical fascial cleft (*cavum Retzii*)<sup>1</sup>.

When the bladder is empty, it is placed entirely within the pelvis, below the level of the obliterated hypogastric arteries, and below the level of those portions of the ductus deferentes that are in contact with the lateral wall of the pelvis; after they cross the ureters, the ductus deferentes come into contact with the fundus of the bladder. As the viscus fills, its fundus, being more or less fixed, is only slightly depressed, while its superior surface gradually rises into the abdominal cavity, carrying with it its peritoneal covering and at the same time rounding off the posterior and lateral borders.

### **Distended Bladder**

When the bladder is moderately full, it contains about 0.5 L and assumes an oval form; the long diameter of the oval measures

about 12 cm and is directed cranialward and ventralward. In this condition it presents a posterosuperior and an anteroinferior surface and two lateral surfaces—a fundus and a summit.

The **posterosuperior surface** is covered by peritoneum. Dorsally, it is separated from the rectum by the rectovesical excavation, while its anterior part is in contact with the coils of the small intestine.

The **anteroinferior surface** is devoid of peritoneum; it rests against the pubic bones, above which it is in contact with the back of the anterior abdominal wall. The caudal parts of the lateral surfaces are destitute of peritoneum and are in contact with the lateral walls of the pelvis. The line of peritoneal reflection from the lateral surface is raised to the level of the obliterated hypogastric artery.

The **fundus** undergoes little alteration in position, being only slightly lowered. It exhibits, however, a narrow triangular area, which is separated from the rectum merely by the rectovesical fascia. This area is

<sup>1</sup>Anders Adolf Retzius (1796–1860): A Swedish anatomist (Stockholm).

**Fig. 17-28.** Male pelvic organs and perineum seen from left side after removal of left pelvic wall. Bladder and rectum moderately distended. (Eycleshymer and Jones.)

bounded below by the prostate, above by the rectovesical fold of peritoneum, and laterally by the ductus deferentes. The ductus deferentes frequently come in contact with each other above the prostate, and under such circumstances the lower part of the triangular area is obliterated. The line of reflection of the peritoneum from the rectum to the bladder appears to undergo little or no change when the bladder is distended; it is situated about 10 cm from the anus.

The **summit** is directed cranialward and ventralward above the point of attachment of the median umbilical ligament, and hence the peritoneum that follows the ligament forms a pouch of varying depth between the summit of the bladder and the anterior abdominal wall.

### **Bladder in the Child**

In the newborn child the internal urethral orifice is at the level of the upper border of the symphysis pubis (Figs. 17-29; 17-30); the bladder therefore lies relatively at a much higher level in the infant than in the adult. Its anterior surface is in contact with about the lower two-thirds of that part of the abdominal wall which lies between the symphysis pubis and the umbilicus. Its fundus is clothed with peritoneum as far as the level of the internal orifice of the urethra. Although the bladder of the infant is usually described as an abdominal organ, only about one-half of it lies above the plane of the superior aperture of the pelvis. The internal urethral orifice sinks rapidly during the first

**FIG. 17-29.** Sagittal section through the pelvis of a newly born male child.

three years, and then more slowly until the ninth year, after which it remains stationary until puberty, when it again slowly descends and reaches its adult position.

### **Female Bladder**

In the female, the bladder is in relation dorsally with the uterus and the upper part of the vagina (Fig. 17-31). It is separated from the anterior surface of the body of the uterus by the vesicouterine excavation, but below the level of this excavation it is connected to the front of the cervix uteri and the upper

part of the anterior wall of the vagina by areolar tissue. When the bladder is empty the uterus rests upon its superior surface. The female bladder is said by some to be more capacious than that of the male, but probably the opposite is the case.

### **Ligaments**

The bladder is held in position by ligamentous attachments at its inferior portion or base, that is, near the exit of the urethra, and at the vertex. The remainder of the wall, enclosed in subserous fascia, is free to move

**FIG. 17-30.** Sagittal section through the pelvis of a newly born female child.

**FIG. 17-31.** Median sagittal section of female pelvis.

during the expansion and contraction of filling and emptying.

The base of the bladder is attached to the internal investing layer of deep fascia on the pubic bone by strong fibrous bands that may contain muscle fibers, the pubovesicales. In the male, because the prostate is firmly bound to the bladder in this region, these attachments are between the prostate and pubic bone rather than directly to the bladder, and they are named the **medial** and **lateral puboprostatic ligaments**. In the female the attachments are directly between bladder and pubis and are therefore called the **pubovesical ligaments**.

The base of the bladder is secured posteriorly to the side of the rectum and the sacrum by condensations of the subserous fascia underlying the sacrogenital folds. They are called the **rectovesical ligaments**, or, since they may contain smooth muscle bundles, the **rectovesical muscles**.

The **median umbilical ligament** is a fibrous or fibromuscular cord, the remains of the urachus, which extends from the vertex of the bladder to the umbilicus. It is broad at its

attachment to the bladder and becomes narrow as it nears the umbilicus.

In addition to these fibrous or true ligaments, there is a series of folds where the peritoneum is reflected from the bladder to the abdominal wall; these are called **false ligaments of the bladder**. Anteriorly there are three folds: the **median umbilical fold** on the median umbilical ligament, and two **lateral umbilical folds** on the obliterated umbilical arteries. The reflections of the peritoneum onto the side wall of the pelvis form the **lateral false ligaments**, while the **sacrogenital folds** constitute **posterior false ligaments**.

### **Interior of the Bladder**

The mucous membrane lining the greater part of the bladder is loosely attached to the muscular coat, and appears wrinkled or folded when the bladder is contracted (Fig. 17-32); in the distended condition the folds are effaced. Over a small triangular area, termed the **trigone**, immediately above and behind the internal orifice of the urethra, the

FIG. 17-32. The interior of bladder.

mucous membrane is firmly bound to the muscular coat and is always smooth. The anterior angle of the trigone is formed by the internal orifice of the urethra; its posterolateral angles are formed by the orifices of the ureters. Stretching dorsal to the latter openings is a slightly curved ridge, the **torus uretericus**, which forms the base of the trigone and is produced by an underlying bundle of nonstriated muscular fibers. The lateral parts of this ridge extend beyond the openings of the ureters and are named the **plicae uretericae**; they are produced by the terminal portions of the ureters as they traverse the bladder wall obliquely. When the bladder is illuminated, the torus uretericus appears as a pale band and forms an important guide during the operation of introducing a catheter into the ureter.

The **orifices of the ureters** are placed at the posterolateral angles of the trigone and are usually slit-like in form. In the contracted bladder, they are about 2.5 cm apart and about the same distance from the internal urethral orifice; in the distended viscus, these measurements may be increased to about 5 cm.

The **internal urethral orifice** is placed at the apex of the trigone in the most dependent part of the bladder; it usually has a somewhat crescentic form. The mucous membrane immediately behind it presents a slight elevation, the **uvula vesicae**, caused by the middle lobe of the prostate.

## Structure

The bladder is composed of the four coats: **serous, muscular, submucous, and mucous** (Fig. 17-33).

**SEROUS COAT.** The serous coat is a partial one and is derived from the peritoneum. It invests the superior surface and the upper parts of the lateral surfaces, and is reflected from these onto the abdominal and pelvic walls.

**MUSCULAR COAT.** The muscular coat consists of three layers of smooth muscular fibers: an external layer, composed of fibers having for the most part a longitudinal arrangement; a middle layer, in which the fibers are arranged more or less in a circular manner; and an internal layer, in which the fibers have a general longitudinal arrangement (Fig. 17-34).

The fibers of the external layer arise from the posterior surface of the body of the pubis in both sexes (*musculi pubovesicales*), and in the male from the adjacent part of the prostate and its capsule. They pass, in a more or less longitudinal manner, up the inferior surface of the bladder, over its vertex, and then descend along its fundus, to become attached to the prostate in the male and to the front of the vagina in the female. At the sides of the bladder, the fibers are arranged obliquely and intersect one another.

FIG. 17-33. Vertical section of bladder wall.

**Fig. 17-34.** Diagram of the muscle of the bladder. (After McCrea.)

This layer has been named the **detrusor urinae muscle**.

The fibers of the middle circular layer are thinly and irregularly scattered on the body of the organ, and although to some extent they are placed transversely to the long axis of the bladder, they are largely arranged obliquely. Toward the lower part of the bladder, around the internal urethral orifice, they are disposed in a thick circular layer, forming the **sphincter vesicae**, which is continuous with the muscular fibers of the prostate.

The *internal longitudinal layer* is thin. Its fasciculi have a reticular arrangement but with a tendency to assume for the most part a longitudinal direction. Two bands of oblique fibers, originating behind the orifices of the ureters, converge to the back part of the prostate and are inserted by means of a fibrous process into the middle lobe of that organ. They are the **muscles of the ureters**, described in the early 19th century by Sir C. Bell, who supposed that during the contraction of the bladder they serve to retain the oblique direction of the ureters and so prevent the reflux of the urine into them.

**SUBMUCOUS COAT.** The submucous coat consists of a layer of areolar tissue connecting the muscular and mucous coats and intimately united to the latter.

**MUCOUS COAT.** The mucous coat is thin, smooth, and a pale rose color. It is continuous above through the ureters with the lining membrane of the renal tubules and below with that of the urethra. The loose texture of the submucous layer allows the mucous coat to be thrown into folds or *rugae* when the

bladder is empty. Over the trigone the mucous membrane is closely attached to the muscular coat, and is not thrown into folds, but is smooth and flat. The epithelium covering it is transitional, consisting of a superficial layer of polyhedral flattened cells, each with one, two, or three nuclei; beneath these is a stratum of large club-shaped cells, with their narrow extremities directed downward and wedged between smaller spindle-shaped cells, containing oval nuclei (Fig. 17-33). The epithelium varies accordingly as the bladder is distended or contracted. In the former condition the superficial cells are flattened and those of the other layers are shortened; in the latter they present the appearance described above. There are no true glands in the mucous membrane of the bladder, though certain mucous follicles that occur especially near the neck of the bladder have been regarded as such.

**VESSELS AND NERVES.** The **arteries** supplying the bladder are the superior, middle, and inferior vesical arteries, derived from the internal iliac artery. The obturator and inferior gluteal arteries also supply small visceral branches to the bladder, and in the female additional branches are derived from the uterine and vaginal arteries.

The **veins** form a complicated plexus on the inferior surface and the fundus near the prostate; they end in the internal iliac veins.

The **lymphatics** are described in Chapter 10.

The **nerves** of the bladder are (1) fine medullated fibers from the third and fourth sacral nerves, and (2) nonmedullated fibers from the hypogastric plexus. They are connected with ganglia in the outer and submucous coats and are finally distributed, all as nonmedullated fibers, to the muscular layer and epithelial lining of the viscus.

**VARIATIONS.** A defect of development is known as *extroversion of the bladder*. In this condition the lower part of the abdominal wall and the anterior wall of the bladder are wanting, so that the fundus of the bladder appears on the abdominal surface and is pushed forward by the pressure of the viscera within the abdomen, forming a red vascular tumor on which the openings of the ureters are visible. The penis, except the glans, is rudimentary and is cleft on its dorsal surface, exposing the floor of the urethra, a condition known as *epispadias*. The pelvic bones are also arrested in development.

## MALE URETHRA

The **male urethra** (Fig. 17-35) extends from the internal urethral orifice in the urinary bladder to the external urethral orifice at the

**Fig. 17-35.** The male urethra laid open on its anterior (upper) surface.

end of the penis. It has a double curve in the ordinary relaxed state of the penis (Fig. 17-27). Its length varies from 17.5 to 20 cm, and it is divided into three portions, **prostatic**, **membranous**, and **spongy**, the structure and relations of which are essentially different. Except during the passage of the urine or semen, the greater part of the urethral canal is a mere transverse cleft or slit, with its surfaces in contact. At the external orifice the slit is vertical, in the membranous portion it is irregular or stellate, and in the prostatic portion it is somewhat arched.

### Prostatic Portion

This portion, the widest and most dilatable part of the canal, is about 3 cm long. It runs almost vertically through the prostate from its base to its apex, lying nearer its anterior than its posterior surface. The form

of the canal is spindle-shaped, being wider in the middle than at either extremity and narrowest below, where it joins the membranous portion. A transverse section of the canal as it lies in the prostate is horseshoe-shaped, with the convexity directed ventralward.

Upon the posterior wall or floor is a narrow longitudinal ridge, the **urethral crest**, formed by an elevation of the mucous membrane and its subjacent tissue. It is 15 to 17 mm long and about 3 mm high. On either side of the crest is a slightly depressed fossa, the **prostatic sinus**, the floor of which is perforated by numerous apertures, the **orifices of the prostatic ducts** from the lateral lobes of the prostate; the ducts of the middle lobe open behind the crest. At the distal part of the urethral crest, below its summit, is a median elevation, the **colliculus seminalis** or **verumontanum**, upon or within the margins of which are the orifices of the prostatic utricle and the slit-like openings of the ejaculatory ducts.

The **prostatic utricle** forms a cul-de-sac about 6 mm long, which runs upward and backward in the substance of the prostate behind the middle lobe. Its walls are composed of fibrous tissue, muscular fibers, and mucous membrane, and numerous small glands open on its inner surface. Some authors call it the **uterus masculinus**, because it is developed from the united lower ends of the atrophied paramesonephric or Müllerian ducts, and therefore is homologous with the uterus and vagina in the female.

### Membranous Portion

This portion is the shortest, least dilatable, and with the exception of the external orifice, the narrowest part of the canal. It extends between the apex of the prostate and the bulb of the penis, perforating the urogenital diaphragm about 2.5 cm from the pubic symphysis. The dorsal part of the urethral bulb lies in apposition with the superficial layer of the urogenital diaphragm, but its upper portion diverges somewhat from this fascia. The anterior wall of the membranous urethra is thus prolonged for a short distance ventral to the urogenital diaphragm; it measures about 2 cm in length, while the posterior wall, which is between the two fasciae of the diaphragm, is only 1.25 cm long.

The membranous portion of the urethra is completely surrounded by the fibers of the

sphincter urethrae. Ventral to it, the deep dorsal vein of the penis enters the pelvis between the transverse ligament of the pelvis and the arcuate pubic ligament; on either side near its termination are the bulbourethral glands.

### *Spongiose Portion*

The spongiose portion (penile portion) is the longest part of the urethra and is contained in the corpus spongiosum. It is about 15 cm long, and extends from the termination of the membranous portion to the external urethral orifice. Commencing at the superficial layer of the urogenital diaphragm, it passes ventralward and upward to the front of the symphysis pubis, and then, in the flaccid penis, it bends downward. It is narrow and has a uniform size in the body of the penis, measuring about 6 mm in diameter; it is dilated proximally, within the bulb, and again anteriorly within the glans penis, where it forms the **fossa navicularis urethrae**.

### *External Urethral Orifice*

This is the most contracted part of the urethra; it is a vertical slit, about 6 mm long, bounded on each side by a small labium.

The lining membrane of the urethra, especially that on the floor of the spongiose portion, contains the orifices of numerous mucous glands and follicles situated in the submucous tissue; these are named the **urethral glands** (of Littré)<sup>1</sup>. There are also small pit-like recesses, or **lacunae**, of varying sizes. These orifices are directed distalward, so that they may easily intercept the point of a catheter in its passage along the canal. One of these lacunae, larger than the rest, is situated on the upper surface of the fossa navicularis; it is called the **lacuna magna**. The bulbourethral glands open into the cavernous portion about 2.5 cm distal to the inferior fascia of the urogenital diaphragm.

### *Structure*

The urethra is composed of mucous membrane supported by a submucous tissue that connects it with the various structures through which it passes.

**MUCOUS COAT.** The mucous coat is continuous with the mucous membrane of the bladder, ureters, and kidneys; externally, it is continuous with the integument covering the glans penis. It is prolonged into the ducts of the glands that open into the urethra, viz., the bulbourethral glands and the prostate, and into the ductus deferentes and seminal vesicles through the ejaculatory ducts. In the spongiose and membranous portions, the mucous membrane is arranged in longitudinal folds when the tube is empty. Small papillae are found upon it, near the external urethral orifice. Its epithelial lining is columnar except near the external orifice, where it is squamous and stratified.

**SUBMUCOSA.** The submucosa has a characteristic structure. It is composed of a thick stroma of connective tissue rich in elastic fibers. These fibers connect freely with the spongy tissue of the penis, which prevents ready removal of the mucosa in this region. However, in the membranous and prostatic portions, which change but little during erection, the urethra is quite free and may on dissection be stripped readily.

**VESSELS AND NERVES.** The **urethral artery**, a branch of the internal pudendal artery in the perineum, supplies the membranous and penile urethra. The **veins** of the urethra and corpus spongiosum drain into the deep vein of the penis and the pudendal plexus. The **lymphatics** are described in Chapter 10. The **nerves** come from the pudendal nerve.

**CONGENITAL DEFECTS.** The defect most frequently met is one in which there is a cleft of the floor of the urethra owing to an arrest of union in the midline. This is known as *hypospadias*, and the cleft may vary in extent. In the simplest and most common form, the deficiency is confined to the glans penis. The urethra ends at the point where the extremity of the prepuce joins the body of the penis, in a small valve-like opening. The prepuce is also cleft on its undersurface and forms a sort of hood over the glans. There is a depression on the glans in the position of the normal meatus. This condition produces no disability and requires no treatment.

In more severe cases the spongiose portion of the urethra is cleft throughout its entire length, and the opening of the urethra occurs at the junction of the penis and the scrotum. The undersurface of the penis in the midline has a furrow lined by a moist mucous membrane, on either side of which is often more or less dense fibrous tissue stretching from the glans to the opening of the urethra, which prevents complete erection from taking place. Great discomfort is induced during micturition and sexual intercourse is impossible. The condition may be remedied by a series of plastic operations.

The worst form of this condition occurs when the

<sup>1</sup>Alexis Littré (1658–1725): A French surgeon (Rheims and Paris).

urethra is deficient as far back as the perineum, and the scrotum is cleft. The penis is small and bound down between the two halves of the scrotum, resembling a hypertrophied clitoris. The testes are often undescended. The condition of parts, therefore, greatly resembles the external genitalia of the female, and many children, the victims of this malformation, have been raised as girls. The halves of the scrotum, deficient of testes, resemble the labia, the cleft between them looks like the orifice of the vagina, and the diminutive penis is mistaken for an enlarged clitoris.

A more uncommon form of malformation involves an apparent deficiency of the upper wall of the urethra; this is named *epispadias*. The deficiency may vary in extent; complete deficiency is associated with extroversion of the bladder. In less extensive cases without extroversion, there is an infundibuliform opening into the bladder. The penis is usually dwarfed and turned upward, so that the glans lies over the opening. Congenital stricture also occurs occasionally, and in such cases multiple strictures may be present throughout the whole length of the spongy portion.

## FEMALE URETHRA

The **female urethra** (Fig. 17-31) is a narrow membranous canal, about 4 cm long, extending from the bladder to the external orifice in the vestibule. It is dorsal to the symphysis pubis and embedded in the anterior wall of the vagina. Its direction is obliquely downward and forward; it is slightly curved, with the concavity directed forward. Its diameter when undilated is about 6 mm. It perforates the fasciae of the urogenital diaphragm, and its external orifice is situated directly ventral to the vaginal opening and about 2.5 cm dorsal to the glans clitoridis. The lining membrane is thrown into longitudinal folds, one of which, placed along the floor of the canal, is termed the **urethral crest**. Many small urethral glands open into the urethra. The largest of these are the paraurethral glands (of Skene), the ducts of which open just within the urethral orifice.

## Structure

The female urethra consists of three coats: **muscular, erectile, and mucous**.

**COATS.** The **muscular coat** is continuous with that of the bladder; it extends the whole length of the tube, and consists of circular fibers. In addition, between the superior and inferior fasciae of the urogenital diaphragm,

the female urethra is surrounded by the sphincter urethrae, as in the male.

A thin layer of **spongy erectile tissue**, containing a plexus of large veins intermixed with bundles of unstripped muscular fibers, lies immediately beneath the mucous coat.

The **mucous coat** is continuous externally with that of the vulva, and internally with that of the bladder. It is lined by stratified squamous epithelium, which becomes transitional near the bladder. Its external orifice is surrounded by a few mucous follicles.

**VESSELS AND NERVES.** The **arteries** are derived from the inferior vesical and internal pudendal arteries. The **veins** drain into the vesical and vaginal veins. The **lymphatics** are described in Chapter 10. The **nerves** are from the pelvic plexus and pudendal nerves.

## Male Genital Organs

The male genitals include the **testes**, the **ductus deferentes**, the **vesiculae seminales**, the **ejaculatory ducts**, and the **penis**, together with the following accessory structures, viz., the **prostate** and the **bulbourethral glands**.

## TESTES AND THEIR COVERINGS

The **testes** (Figs. 17-36; 17-37) are two parenchymatous organs that produce the semen; they are suspended in the scrotum by the spermatic cords. At an early period of fetal life the testes are contained in the abdominal cavity, behind the peritoneum. Before birth they descend to the inguinal canal, along which they pass, and emerging at the superficial inguinal ring, descend into the scrotum, becoming invested in their course by coverings derived from the serous, muscular, and fibrous layers of the abdominal parietes, as well as by the scrotum.

## Coverings

The coverings of the testes are:

Skin	} Scrotum
Dartos tunic	
External spermatic fascia	
Cremasteric layer	
Internal spermatic fascia	
Tunica vaginalis	

**Fig. 17-36.** The scrotum. The penis has been turned upward and the anterior wall of the scrotum has been removed. On the right side, the spermatic cord, the internal spermatic fascia, and the cremaster muscles are displayed; on the left side the internal spermatic fascia has been divided by a longitudinal incision passing along the front of the cord and the testicle, and a portion of the parietal layer of the tunica vaginalis has been removed to display the testicle and a portion of the head of the epididymis covered by the visceral layer of the tunica vaginalis. (Toldt.)

**SCROTUM.** The scrotum is a cutaneous pouch containing the testes and parts of the spermatic cords. It is divided on its surface into two lateral portions by a ridge or **raphe**, which is continued ventralward to the undersurface of the penis, and dorsalward along the midline of the perineum to the anus. The external aspect of the scrotum varies under different circumstances. Under the influence of warmth and in old and debilitated persons, it becomes elongated and flaccid, but under the influence of cold, and in the young and robust, it is short, corrugated, and closely applied to the testes. Of the two lateral portions, the left hangs lower

than the right, to correspond with the greater length of the left spermatic cord.

The **scrotum** consists of two layers, the **skin** or **integument** and the **dartos tunic**.

**Integument.** The integument is thin, brownish, and generally thrown into folds or rugae. It is provided with sebaceous follicles, the secretion of which has a characteristic odor, and is beset with thinly scattered, crisp kinky hairs, the roots of which are visible through the skin.

**Dartos Tunic.** The dartos tunic contains a thin layer of nonstriated muscular fibers that are continuous around the base of the scrotum with the two layers of the superficial

**FIG. 17-37.** The right testis, exposed by laying open the tunica vaginalis.

fascia of the groin and the perineum. It sends inward a septum, which divides the scrotal pouch into two cavities for the testes, and extends between the raphe and the under-surface of the penis as far as its root.

The dartos tunic is closely united to the skin externally, but is separated from the subjacent parts by a distinct fascial cleft, upon which it glides with the greatest facility. It contains no fat and is highly vascular.

**EXTERNAL SPERMATIC FASCIA.** The external spermatic fascia (*intercrural or intercolumnar fascia*) is a thin membrane prolonged distalward over the cord and testis. It is continuous at the superficial inguinal ring with the aponeurosis of the obliquus externus abdominis and is separated from the enclosing dartos by a fascial cleft.

**CREMASTERIC LAYER.** The cremasteric layer consists of the scattered bundles of the cremaster muscle connected into a continuous membrane by the cremasteric fascia. It forms the *middle spermatic layer* and corresponds to the obliquus internus abdominis and its fasciae.

**INTERNAL SPERMATIC LAYER.** The internal spermatic fascia (*infundibuliform fascia; tunica vaginalis communis*) is a thin membrane that is often difficult to separate from the cremasteric layer but more easily separates from the cord and testis, which it encloses. It is continuous at the deep inguinal ring with the transversalis fascia.

The **tunica vaginalis** is described with the testes.

**VESSELS AND NERVES.** The **arteries** that supply the coverings of the testes are the superficial and deep external pudendal branches of the femoral artery, the superficial perineal branch of the internal pudendal artery, and the cremasteric branch from the inferior epigastric artery. The **veins** follow the course of the corresponding arteries. The **lymphatics** end in the inguinal lymph nodes. The **nerves** are the ilioinguinal and genitofemoral branches of the lumbar plexus, the two superficial perineal branches of the pudendal nerve, and the pudendal branch of the posterior femoral cutaneous nerve.

The scrotum forms an admirable covering for the protection of the testes. These bodies, lying suspended and loose in the cavity of the scrotum and surrounded by serous membrane, are capable of great mobility, and can therefore easily slip about within the scrotum and thus avoid injuries from blows or squeezes. The skin of the scrotum is elastic and capable of great distention, and on account of the looseness and amount of subcutaneous tissue, the scrotum becomes greatly enlarged in cases of edema, to which this part is especially liable as a result of its dependent position.

The **inguinal canal** is described in Chapter 6.

### **Spermatic Cord**

The spermatic cord (Fig. 17-38) extends from the deep inguinal ring, where the structures of which it is composed converge, to the testis. In the abdominal wall, the cord passes obliquely along the inguinal canal, lying at first inferior to the obliquus internus and superior to the fascia transversalis, but

**Fig. 17-38.** Section across the spermatic cord as it lies in the scrotum canal.

nearer the pubis, it rests upon the inguinal and lacunar ligaments, having the aponeurosis of the obliquus externus ventral to it and the inguinal falx dorsal to it. It then escapes at the ring and descends nearly vertically into the scrotum. The left cord is longer than the right; consequently the left testis hangs somewhat lower than the right.

**STRUCTURE OF THE SPERMATIC CORD.** The spermatic cord is composed of arteries, veins, lymphatics, nerves, and the excretory duct of the testis. These structures are connected together by the **internal spermatic fascia**, which is continuous with the subserous fascia of the abdomen at the deep inguinal ring; they are invested by the layers brought down by the testis in its descent.

**Arteries.** The arteries of the cord are the testicular and external spermatic arteries and the artery to the ductus deferens.

The *testicular artery*, a branch of the abdominal aorta, escapes from the abdomen at the deep inguinal ring, and accompanies the other constituents of the spermatic cord along the inguinal canal and through the superficial inguinal ring into the scrotum. It then descends to the testis, and becoming tortuous, divides into several branches, two or three of which accompany the ductus deferens and supply the epididymis, anastomosing with the artery of the ductus deferens. The others supply the substance of the testis.

The *external spermatic artery* is a branch of the inferior epigastric artery. It accompanies the spermatic cord and supplies the coverings of the cord, anastomosing with the testicular artery.

The *artery of the ductus deferens*, a branch of the superior vesical artery is a long, slender vessel that accompanies the ductus deferens, ramifying upon

its coats and anastomosing with the testicular artery near the testis.

**Veins.** The testicular veins (Fig. 9-32) emerge from the back of the testis and receive tributaries from the epididymis. They unite and form a convoluted plexus, the **plexus pampiniformis**, which forms the chief mass of the cord. The vessels composing this plexus are numerous and ascend along the cord in front of the ductus deferens. Below the superficial inguinal ring they unite to form three or four veins, which pass along the inguinal canal, and entering the abdomen through the abdominal inguinal ring, coalesce to form two veins. These again unite to form a single vein that opens on the right side into the inferior vena cava, at an acute angle, and on the left side into the left renal vein, at a right angle.

The **lymphatic vessels** are described in Chapter 10.

The **nerves** are the spermatic plexus from the sympathetic, joined by filaments from the pelvic plexus, which accompany the artery of the ductus deferens.

## Testes

The testes are oval (Fig. 17-37), compressed laterally and suspended in the scrotum by the spermatic cords. They average 4 to 5 cm in length, 2.5 cm in breadth, and 3 cm in the anteroposterior diameter. The weight of one gland varies from 10.5 to 14 gm. Each organ has an oblique position in the scrotum. The cranial extremity is directed ventralward and a little lateralward; the caudal, dorsalward and a little medialward. The anterior convex border faces ventralward and caudalward; the posterior or straight border, to which the cord is attached, dorsalward and cranialward.

The anterior border and lateral surfaces, as well as both extremities of the organ, are convex, free, smooth, and invested by the visceral layer of the tunica vaginalis. The posterior border, to which the cord is attached, receives only a partial investment from that membrane. Lying upon the lateral edge of this posterior border is a long, narrow, flat body named the **epididymis**.

### EPIDIDYMIS

The epididymis consists of a central portion or **body**; an upper enlarged extremity, the **head**; and a lower pointed extremity, the **tail**, which is continuous with the **ductus deferens**, the duct of the testis. The head is intimately connected with the upper end of the testis by means of the efferent ductules of the gland; the tail is connected with the lower end by cellular tissue, and a reflection of the tunica vaginalis. The lateral surface, head, and tail of the epididymis are free and covered by the serous membrane; the body is also completely invested by it, except along its posterior border, while between the body and the testis is a pouch, named the **sinus of the epididymis** (*digital fossa*). The epididymis is connected to the back of the testis by a fold of the serous membrane.

### APPENDAGES OF THE TESTIS AND EPIDIDYMIS

On the proximal extremity of the testis, just beneath the head of the epididymis, is a minute oval, sessile body, the **appendix of the testis**; it is the remnant of the upper end of the Müllerian duct. On the head of the epididymis is a second small stalked appendage (sometimes duplicated); it is named the **appendix of the epididymis** and is usually regarded as a detached efferent duct.

### TUNICS

The testis is invested by three tunics: the **tunica vaginalis**, **tunica albuginea**, and **tunica vasculosa**.

**TUNICA VAGINALIS.** The tunica vaginalis is the serous covering of the testis. It is a pouch of serous membrane derived from the saccus vaginalis of the peritoneum, which in the fetus preceded the descent of the testis from the abdomen into the scrotum. After its descent, the portion of the pouch that extends from the deep inguinal ring to near the upper part of the gland becomes obliterated;

the lower portion remains as a closed sac that invests the testis, and may be described as consisting of a **visceral** and a **parietal lamina** (Fig. 17-37).

**Visceral Lamina.** The visceral lamina covers the greater part of the testis and epididymis, connecting the latter to the testis by means of a distinct fold. From the posterior border of the gland it is reflected onto the internal surface of the scrotal coverings.

**Parietal Lamina.** The parietal lamina is more extensive than the visceral, extending cranialward for some distance ventral and medial to the cord, and reaching below the testis. The inner surface of the tunica vaginalis is smooth and covered by a layer of mesothelial cells. The interval between the visceral and parietal laminae constitutes the cavity of the tunica vaginalis.

The obliterated portion of the saccus vaginalis may generally be seen as a fibrous thread lying in the loose areolar tissue around the spermatic cord. Sometimes this may be traced as a distinct band from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it gradually becomes lost on the spermatic cord. Occasionally no trace of it can be detected. In some cases it happens that the pouch of peritoneum does not become obliterated, but the sac of the peritoneum communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia. In other cases the pouch may contract, but not become entirely obliterated; it then forms a minute canal leading from the peritoneum to the tunica vaginalis.

**TUNICA ALBUGINEA.** The tunica albuginea is the fibrous covering of the testis. It is a dense membrane with a bluish-white color, composed of bundles of white fibrous tissue that interlace in every direction. It is covered by the tunica vaginalis, except at the points of attachment of the epididymis to the testis and along its posterior border, where the testicular vessels enter the gland. It is applied to the tunica vasculosa over the glandular substance of the testis, and at its posterior border, is reflected into the interior of the gland, forming an incomplete vertical septum called the **mediastinum testis** (*corpus Highmori*<sup>1</sup>).

**Mediastinum Testis.** The mediastinum

<sup>1</sup>Nathaniel Highmore (1613-1685): An English surgeon (Sherborne).

testis extends from the upper to near the lower extremity of the gland, and is wider above than below. From its front and sides numerous imperfect septa (*trabeculae*) are given off, which radiate toward the surface of the organ and are attached to the tunica albuginea. They divide the interior of the organ into a number of incomplete lobules that are somewhat cone-shaped, being broad at their bases at the surface of the gland and becoming narrower as they converge to the mediastinum. The mediastinum supports the vessels and ducts of the testis in their passage to and from the substance of the gland.

**TUNICA VASCULOSA.** The tunica vasculosa is the vascular layer of the testis, consisting of a plexus of blood vessels held together by delicate areolar tissue. It clothes the inner surface of the tunica albuginea and the different septa in the interior of the gland and therefore forms an internal investment to all the spaces of which the gland is composed.

**STRUCTURE.** The glandular structure of the testis consists of numerous lobules. Their number, in a single testis, is estimated to be between 250 and 400. They differ in size according to their position, those in the middle of the gland being larger and longer. The lobules (Fig. 17-39) are conical in shape, the base being directed toward the circumference of the organ, the apex toward the mediastinum. Each lobule is contained in one of the intervals between the fibrous septa that extend between the mediastinum

**FIG. 17-39.** Vertical section of the testis, to show the arrangement of the ducts.

testis and the tunica albuginea, and consists of one to three or more minute convoluted tubes, the **seminiferous tubules**.

**Seminiferous Tubules.** The tubules may be separately unraveled by careful dissection under water, and may be seen to commence either by free cecal ends or by anastomotic loops (Fig. 17-40). They are supported by loose connective tissue that contains here and there groups of interstitial cells containing yellow pigment granules. The total number of tubules is estimated at 840, and the average length of each is 70 to 80 cm. Their diameter varies from 0.12 to 0.3 mm. The tubules are pale in early life, but in old age they acquire a deep yellow tinge from containing much fatty matter. Each tubule consists of a basement layer formed of laminated connective tissue containing numerous elastic fibers with flattened cells between the layers and covered externally by a layer of flattened epithelioid cells.

**Basement Membrane.** Within the basement membrane are epithelial cells arranged in several irregular layers, which are not

**Fig. 17-40.** Four seminiferous tubules from human testis showing anastomosing loops. B, branching or fork; D, diverticulum; X, broken end. (Johnson, Anat. Rec., 1934; courtesy of Wistar Institute.)

always clearly separated, but which may be arranged in three different groups. Among these cells may be seen the **spermatozoa** in different stages of development.

(1) Lining the basement membrane and forming the outer zone is a layer of cubical cells, with small nuclei; some of these enlarge to become **spermatogonia**. The nuclei of some of the spermatogonia may be in process of mitotic division (*karyokinesis*). As a consequence, daughter cells are formed, which constitute the second zone (Fig. 17-41).

(2) Within this layer, a number of larger polyhedral cells with clear nuclei are arranged in two or three layers; these are the **intermediate cells** or **spermatocytes**. Most of these cells are in a stage of karyokinetic division, and the cells that result from this division form those of the next layer, the **spermatids**.

(3) The third layer of cells consists of the spermatids, and each of these, without further subdivision, becomes a **spermatozoön**. The spermatids are small polyhedral cells, the nucleus of each of which contains half the usual number of chromosomes. In addition to these three layers, other cells, termed the **supporting cells** (*cells of Sertoli*<sup>1</sup>), are seen. They are elongated and project inward from the basement membrane toward the lumen of the tube. As the spermatozoa develop, they group themselves around the inner extremities of the supporting cells. The nuclear portion of the spermatid, which is partly embedded in the supporting cell, is differentiated to form the head of the spermatozoön, while part of the cell protoplasm forms the middle piece and the tail is produced by an outgrowth from the double centriole of the cell. Ultimately the heads are liberated and the spermatozoa are set free (Fig. 17-42). The structure of the spermatozoön is described in Chapter 2.

In the apices of the lobules, the tubules become less convoluted, assume a nearly straight course, and unite together to form 20 to 30 larger ducts, about 0.5 mm in diameter; these, from their straight course, are called **tubuli recti** (Fig. 17-39).

**Tubuli Recti and Cones.** The **tubuli recti** enter the fibrous tissue of the mediastinum and pass upward and backward, forming, in their ascent, a close network of anastomos-

ing tubes that are merely channels in the fibrous stroma, lined by flattened epithelium and having no proper walls; this constitutes the **rete testis**. At the upper end of the mediastinum, the vessels of the rete testis terminate in 12 to 20 ducts, the **ductuli efferentes**; they perforate the tunica albuginea and carry the seminal fluid from the testis to the epididymis. Their course is at first straight; they then become enlarged and exceedingly convoluted, and form a series of conical masses, the **coni vasculosi**, which together constitute the head of the epididymis. Each cone consists of a single convoluted duct, 15 to 20 cm long, the diameter of which gradually decreases from the testis to the epididymis. Opposite the bases of the cones the efferent vessels open at narrow intervals into a single duct, which constitutes by its complex convolutions the body and tail of the epididymis. When the convolutions of this tube are unraveled, it measures upward of 6 meters in length; it increases in diameter and thickness as it approaches the ductus deferens. The convolutions are held together by fine areolar tissue and by bands of fibrous tissue.

The **tubuli recti** have very thin walls; like the channels of the rete testis, they are lined by a single layer of flattened epithelium. The walls of the ductuli efferentes and the tube of the epididymis are much thicker owing to the presence of muscular tissue, which is principally arranged in a circular manner. These tubes are lined by columnar ciliated epithelium.

**VESSELS AND NERVES.** The **arteries** to the testis are described in Chapter 8; the **veins**, in Chapter 9; the **lymphatics**, in Chapter 10; and the **nerves**, in Chapter 12.

**VARIATIONS.** The testis, developed in the lumbar region, may be arrested or delayed in its transit to the scrotum (*cryptorchism*). It may be retained in the abdomen or it may be arrested at the deep inguinal ring or in the inguinal canal. It may just pass out of the superficial inguinal ring without finding its way to the bottom of the scrotum. When retained in the abdomen, it gives rise to no symptoms or signs other than the absence of the testis from the scrotum, but when it is retained in the inguinal canal it is subjected to pressure and may become inflamed and painful. The retained testis is probably functionally useless, so that a man in whom both testes are retained (*anorchism*) is sterile, though he may not be impotent. The absence of one testis is termed *monorchism*. When a testis is retained in the inguinal canal it is often complicated with a congenital

**FIG. 17-42.** Mature spermatozoa from an adult human male. 1000  $\times$ . (Redrawn from Sobotta.)

hernia, because the funicular process of the peritoneum was not obliterated.

The testis may also descend through the inguinal canal but miss the scrotum and assume some abnormal position. The most common form occurs when the testis, emerging at the subcutaneous inguinal ring, slips down between the scrotum and thigh and comes to rest in the perineum. This is known as *perineal ectopia testis*. With each variety of abnormality in the position of the testis, it is common to find concurrently a congenital hernia, or if a hernia is not actually present, the funicular process is usually patent, almost invariably so if the testis is in the inguinal canal.

The testis, finally reaching the scrotum, may occupy an abnormal position in it. It may be inverted, so that its posterior or attached border is directed forward and the tunica vaginalis is situated behind.

Fluid collections of a serous character are frequently found in the scrotum. To these the term *hydrocele* is applied. The most common form is the ordinary *vaginal hydrocele*, in which the fluid is contained in the sac of the tunica vaginalis, which is normally separated from the peritoneal cavity by the

whole extent of the inguinal canal. In another form, the *congenital hydrocele*, the fluid is in the sac of the tunica vaginalis, but this cavity communicates with the general peritoneal cavity, its tubular process remaining pervious. A third variety, known as an *infantile hydrocele*, occurs when the tubular process becomes obliterated only at its upper part, at or near the deep inguinal ring. It resembles the vaginal hydrocele except in shape, the collection of fluid extending up the cord into the inguinal canal. Fourthly, the funicular process may become obliterated both at the deep inguinal ring and above the epididymis, leaving a central unobliterated portion, which may become distended with fluid, giving rise to a condition known as *encysted hydrocele of the cord*.

**CONGENITAL HERNIA.** Some varieties of oblique inguinal hernia (Fig. 17-43) depend upon congenital defects in the saccus vaginalis, the pouch of peritoneum that precedes the descent of the testis.

Normally this pouch is closed before birth, with closure commencing at two points: at the deep inguinal ring and at the top of the epididymis, and gradually extending until the whole of the intervening portion is converted into a fibrous cord. Failure in the completion of this process produces variations in the relation of the hernial protrusion to the testis and tunica vaginalis. These constitute distinct varieties of inguinal hernia, viz., the hernia of the funicular process and the complete congenital variety.

When the saccus vaginalis remains patent throughout, the cavity of the tunica vaginalis communicates directly with that of the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis, which constitutes the sac of the hernia, and the gut lies in contact with the testis. Though this form of hernia is termed *complete congenital*, the term does not imply that the hernia existed at birth, but merely that a condition is present that may allow the descent of the hernia at any moment. As a matter of fact, congenital hernias frequently do not appear until adult life.

When the processus vaginalis is occluded at the lower point only, i.e., just above the testis, the intestine descends into the pouch of peritoneum as far as the testis, but is prevented from entering the sac of the tunica vaginalis by the septum that has formed

**FIG. 17-43.** Varieties of oblique inguinal hernia. See also Figure 17-10.

between it and the pouch. This is known as *hernia into the funicular process* or *incomplete congenital hernia*; it differs from the former in that instead of enveloping the testis, it lies above it.

### DUCTUS DEFERENS

The **ductus deferens** (*vas deferens*; *seminal duct*), the excretory duct of the testis, is the continuation of the canal of the epididymis. Commencing at the lower part of the tail of the epididymis, it is at first tortuous, but gradually becomes less twisted as it ascends along the posterior border of the testis and medial side of the epididymis, and traverses the inguinal canal to the deep inguinal ring as a constituent of the spermatic cord (Fig. 17-38). Here it separates from the

other structures of the cord, curves around the lateral side of the inferior epigastric artery, and ascends for about 2.5 cm ventral to the external iliac artery. It is next directed dorsalward and slightly caudalward, and crossing the external iliac vessels obliquely, enters the pelvic cavity, where it lies between the peritoneal membrane and the lateral wall of the pelvis. There it descends on the medial side of the obliterated umbilical artery and the obturator nerve and vessels. It then crosses ventral to the ureter, and reaching the medial side of this tube, bends to form an acute angle, and runs medialward and slightly ventralward between the fundus of the bladder and the upper end of the seminal vesicle (Fig. 17-44). Reaching the medial side of the seminal vesicle, it is di-

**FIG. 17-44.** The fundus of the bladder showing the seminal vesicles, ductus deferens, ejaculatory ducts, and the prostate.

rected caudalward and medialward in contact with it, gradually approaching the opposite ductus. Here it lies between the fundus of the bladder and the rectum, where it is enclosed, together with the seminal vesicle, in a sheath derived from the rectovesical portion of the subserous fascia. Lastly, it is directed downward to the base of the prostate, where it becomes greatly narrowed, and is joined at an acute angle by the duct of the seminal vesicle to form the ejaculatory duct, which traverses the prostate behind its middle lobe and opens into the prostatic portion of the urethra, close to the orifice of the prostatic utricle.

The ductus deferens presents a hard and cord-like sensation to the palpating fingers; its walls are dense and its canal is extremely small. At the fundus of the bladder it becomes enlarged and tortuous, and this portion is termed the **ampulla**. A small triangular area of the fundus of the bladder, between the ductus deferentes laterally and the peritoneum of the bottom of the rectovesical excavation, is in contact with the rectum.

### *Ductuli Aberrantes*

A long narrow tube, the **ductulus aberrans inferior** (*vas aberrans of Haller*<sup>1</sup>), is occasionally found connected with the lower part of the canal of the epididymis or with the commencement of the ductus deferens. Its length varies from 3.5 to 35 cm, and it may become dilated toward its extremity; more commonly it retains the same diameter throughout. Its structure is similar to that of the ductus deferens. Occasionally it is found unconnected with the epididymis. A second tube, the **ductulus aberrans superior**, occurs in the head of the epididymis; it is connected with the rete testis.

### *Paradidymis (organ of Giralde's<sup>2</sup>)*

This term is applied to a small collection of convoluted tubules situated in front of the lower part of the cord above the head of the epididymis. These tubes are lined with co-

lumbar ciliated epithelium and probably represent the remains of a part of the Wolffian body.

### *Structure*

The ductus deferens consists of three coats: an **external** or **areolar coat**, a **muscular coat**, and an **internal** or **mucous coat**.

In the greater part of the tube, the muscular coat consists of two layers of unstriated muscular fiber: an outer longitudinal layer, and an inner circular layer. In addition, at the commencement of the ductus is a third layer, consisting of longitudinal fibers placed internal to the circular stratum, between it and the mucous membrane. The internal or mucous coat is pale and arranged in longitudinal folds. The mucous coat is lined by columnar epithelium, which is nonciliated throughout the greater part of the tube. A variable portion of the testicular end of the tube is lined by two strata of columnar cells, and the cells of the superficial layer are ciliated.

**VESSELS AND NERVES.** The **artery of the ductus deferens**, a branch of the superior vesical artery, is a long slender vessel that accompanies the ductus, ramifying upon its coats and anastomosing with the testicular artery near the testis. The ampulla is supplied from the middle and inferior vesical and middle rectal arteries. The **veins** drain into the pampiniform plexus, the vesical veins, and prostatic plexus. The **lymphatics** are described in Chapter 10. The **nerves** are from the pelvic plexus accompanying the artery.

### **SEMINAL VESICLES**

The **seminal vesicles** (Fig. 17-44) are two lobulated membranous pouches, placed between the fundus of the bladder and the rectum, which secrete a fluid to be added to the secretion of the testes. Carefully executed necropsies have shown that in man the seminal vesicles do not store sperm, as the name implies. They are usually about 7.5 cm long, but vary in size, not only in different individuals but also in the same individual on the two sides. The **ventral surface** is in contact with the fundus of the bladder, extending from near the termination of the ureter to the base of the prostate. The **dorsal surface** rests upon the rectum, from which it is sepa-

<sup>1</sup>Albrecht von Haller (1708-1777): A Swiss physiologist (Bern and Göttingen).

<sup>2</sup>Joachim Albin Cardozo Cazado Giralde's (1808-1875): A Portuguese surgeon (Paris).

rated by the rectovesical fascia. The **upper extremities** of the two vesicles diverge from each other and are in relation with the ductus deferentes and the terminations of the ureters; these are partly covered by peritoneum. The **lower extremities** are pointed and converge toward the base of the prostate. The ampullae of the ductus deferentes lie along their medial margin.

Each vesicle consists of a single tube coiled upon itself and giving off several irregular blind diverticula; the separate coils, as well as the diverticula, are bound together by fibrous tissue. When uncoiled, the tube is about the diameter of a quill (5 mm) and varies in length from 10 to 15 cm. It ends superiorly in a cul-de-sac. The inferior extremity becomes constricted into a narrow straight duct that joins with the corresponding ductus deferens to form the ejaculatory duct.

### Structure

The seminal vesicles are composed of three coats: an **external** or **areolar coat**; a **middle** or **muscular coat**, thinner than that in the ductus deferens and arranged in an outer longitudinal and an inner circular layer; and an **internal** or **mucous coat**, which is pale, whitish brown, and has a delicate reticular structure. The epithelium is columnar, and in the diverticula goblet cells are present, the secretion of which increases the bulk of the seminal fluid.

**VESSELS AND NERVES.** The **arteries** that supply the seminal vesicles are derived from the middle and inferior vesical and middle rectal arteries. The **veins** and **lymphatics** accompany the arteries. The **nerves** are derived from the pelvic plexuses.

### EJACULATORY DUCT

The **ejaculatory duct** (Figs. 17-27; 17-45), one on either side of the midline, is formed by the union of the duct from the seminal vesicle with the ductus deferens; it is about 2 cm long. It commences at the base of the prostate, and runs ventralward and caudalward between its middle and lateral lobes and along the sides of the prostatic utricle; it ends in a slit-like orifice close to or just within the margins of the utricle. The ducts diminish in size and also converge toward their terminations.

### Structure

The coats of the ejaculatory ducts are extremely thin. They are: an **outer fibrous layer**, which is almost entirely lost after the entrance of the ducts into the prostate; a **layer of muscular fibers** consisting of a thin outer circular layer and an inner longitudinal layer; and **mucous membrane**.

### THE PENIS

The **penis** is attached to the front and sides of the pubic arch. In the flaccid condition it is cylindrical, but when erect it assumes the form of a triangular prism with rounded angles, one side of the prism forming the dorsum. It is composed of three cylindrical masses of cavernous tissue bound together by fibrous tissue and covered with skin. The two lateral masses are known as the **corpora cavernosa penis**; the third mass is median and is termed the **corpus spongiosum penis**, which contains the greater part of the urethra (Figs. 17-47; 17-48).

The integument covering the penis is remarkable for its thinness, its dark color, its looseness of connection with the deeper parts of the organ, and its absence of adipose tissue. At the root of the penis it is continuous with that over the pubes, scrotum, and perineum. At the neck it leaves the surface and becomes folded upon itself to form the **prepuce** or foreskin. The internal layer of the prepuce is directly continuous along the line of the neck with the integument over the glans. Immediately behind the external urethral orifice it forms a small secondary reduplication, attached along the bottom of a depressed median raphe, which extends from the meatus to the neck; this fold is termed the **frenulum** of the prepuce.

The integument covering the glans is continuous with the urethral mucous membrane at the orifice; it is devoid of hairs, but projecting from its free surface are a number of small, sensitive papillae. Scattered **preputial glands** (of Tyson<sup>1</sup>) are present on the neck of the penis and inner layer of the prepuce. They secrete a sebaceous material with a peculiar odor that readily undergoes decomposition; when mixed with discarded epithe-

**FIG. 17-45.** Anterior view of the seminal vesicles, the ampullae of the ductus deferentes, the prostate gland and the prostatic urethra. The anterior walls of the left ampulla, left seminal vesicle and the prostatic urethra have been cut away. The lower right figure shows a more detailed view of the prostatic urethra and the orifices of the prostatic and ejaculatory ducts.

lial cells it is called **smegma**. The prepuce covers a variable amount of the glans and is separated from it by a potential space—the **preputial space**—which has two shallow fossae, one on either side of the frenulum.

### **Fascia**

The **subcutaneous fascia of the penis** is directly continuous with that of the scrotum, and like it, contains a **dartos** tunic with its layer of scattered smooth muscle cells. It is not divisible into a superficial and a deep layer and it contains no adipose tissue. A fascial cleft between the superficial and deep fasciae gives the skin great movability.

The **deep fascia of the penis** (Buck's fascia<sup>1</sup>) (Fig. 17-46) forms a tubular investment for the shaft of the penis as far distally as the

corona glandis. Proximally, it invests the crura and bulb and is firmly attached with them to the ischiopubic rami and the superficial layer of the urogenital diaphragm. At the anterior or distal extremities of the bulbospongiosus and ischiocavernosi muscles, it splits into a superficial and deep lamina. The superficial lamina covers the superficial surface of these muscles as the external perineal fascia of the perineum; the deep lamina is the continuation of the proper deep fascia of the penis (Buck's fascia). A septum of fascia extends inward between the corpora cavernosa and corpus spongiosum penis, providing separate tubular investments for these columns of erectile tissue.

**CLINICAL CONSIDERATIONS.** The deep fascia of the penis (Buck's fascia) encloses the organ in a strong capsule. An abscess, a hematoma, or an extravasation of urine from rupture of the penile urethra would be confined to the penis by this envelope. A rupture of the urethra in its membranous portion,

<sup>1</sup>Gurdon Buck (1807-1877): An American surgeon (New York).

Fig. 17-46. Fasciae of pelvis and perineum in median sagittal section. Diagram.

however, would allow urine to enter the fascial cleft that is between the deep and superficial fasciae and is continuous with the cleft in the scrotum, under Colles' fascia, and under Scarpa's fascia.

### Corpora Cavernosa Penis

The distal three-fourths of these two cylindrical masses of erectile tissue are intimately bound together and make up the greater part of the shaft of the penis (Fig. 17-47). At the pubic symphysis, however, their posterior portions diverge from each other as two gradually tapering structures called the **crura**.

The corpora retain a uniform diameter in the shaft and terminate anteriorly in a bluntly rounded extremity approximately 1 cm from the end of the penis, being embedded in a cap formed by the glans penis.

The corpora cavernosa penis are surrounded by a strong fibrous envelope consisting of superficial and deep fibers. The superficial fibers have a longitudinal direction and form a single tube that encloses both corpora. The deep fibers are arranged circularly around each corpus, and form the

**septum of the penis** by their junction in the median plane. This is thick and complete behind but imperfect in front, where it consists of a series of vertical bands arranged like the teeth of a comb; it is therefore

Fig. 17-47. The ventral aspect of the corpora cavernosa penis and the corpus spongiosum penis. These cylindrical masses of tissue are shown in the erect position with the glans and distal part of the corpus spongiosum detached from the corpora cavernosa and turned to the right.

named the **septum pectiniforme**. A shallow groove that marks their junction on the upper surface lodges the deep dorsal vein of the penis, while a deeper and wider groove between them on the undersurface contains the corpus spongiosum penis.

Each **crus penis**, the tapering posterior portion of a corpus cavernosum penis, terminates just ventral to the tuberosity of the ischium in a bluntly pointed process, and as it meets its fellow, it has a slight enlargement, the bulb of the corpus cavernosum penis. The crus is bound firmly to the ramus of the ischium and pubis and is enclosed by the fibers of the ischiocavernosus muscle.

### *Corpus Spongiosum Penis*

This part of the penis contains the penile urethra (Fig. 17-47). Its middle portion, in the shaft of the penis, is a uniform cylinder somewhat smaller than a corpus cavernosum penis. At each end it expands, the distal extremity forming the glans penis, the proximal forming the **bulb of the penis**. Between the expansions, it lies in the groove on the undersurface of the corpora cavernosa penis.

The **glans penis** is the anterior end of the corpus spongiosum expanded into an obtuse cone similar to the cap of a mushroom. It is molded over and securely attached to the blunt extremity of the corpora cavernosa penis, and extends farther over their dorsal than their ventral surfaces. Its periphery is larger in diameter than the shaft, projecting in a rounded border, the **corona glandis**. Proximal to the corona is a constriction forming the **retroglandular sulcus** and the **neck of the penis**. At the summit of the glans is the slit-like external orifice of the urethra.

The **bulb** is the conical enlargement of the proximal 4 or 5 cm of the corpus spongiosum. It is just superficial to the urogenital diaphragm, the superficial layer of which blends with its fibrous capsule and is called the ligament of the bulb. It is enclosed by the fibers of the bulbospongiosus muscle.

The urethra enters the corpus spongiosum 1 or 2 cm from the posterior extremity of the bulb by piercing the dorsal surface, i.e., the surface that blends with the urogenital diaphragm. The posterior most expanded portion of the bulb, accordingly, projects backward toward the anus beyond the entrance of the urethra.

### *Ligaments*

The **fundiform ligament** is an extensive thickening of the deep layer of subcutaneous fascia (Scarpa's<sup>1</sup>) of the anterior abdominal wall just above the pubis where it is firmly attached to the rectus sheath. The fibrous bands extend down to the dorsum and sides of the root of the penis. The **suspensory ligament**, shorter than the fundiform, is a strong fibrous triangle derived from the external investing deep fascia, which attaches the dorsum of the root of the penis to the inferior end of the linea alba, the symphysis pubis, and the arcuate pubic ligament. Serving as ligaments also are the attachments of the crura to the ischiopubic rami and of the bulb to the urogenital diaphragm, which have been described previously.

### *Muscles*

The voluntary muscles of the penis are the bulbospongiosus, ischiocavernosus, and the transversus perinei superficialis.

### *Structure of the Penis*

From the internal surface of the fibrous envelope, tunica albuginea, of the corpora cavernosa penis, as well as from the sides of the septum, numerous bands or cords are given off that cross the interior of the corpora cavernosa in all directions, subdividing them into separate compartments and giving the entire structure a spongy appearance (Fig. 17-48). These bands and cords are called **trabeculae**; they consist of white fibrous tissue, elastic fibers, and plain muscular fibers. In them are contained numerous arteries and nerves.

The component fibers that form the trabeculae are larger and stronger around the circumference than at the centers of the corpora cavernosa; they are also thicker proximally than distally. The interspaces or cavernous spaces (blood sinuses), on the contrary, are larger at the center than at the circumference, their long diameters being directed transversely. They contain blood and are lined by a layer of flat cells similar to those in the endothelial lining of veins.

The fibrous envelope of the corpus spongiosum is thinner, whiter, and more elastic

<sup>1</sup>Antonio Scarpa (1747-1832): An Italian anatomist (Pavia).

**FIG. 17-48.** Section of corpus cavernosum penis in a nondistended condition. (Cadiat.) a, Trabeculae of connective tissue, with many elastic fibers and bundles of plain muscular tissue; b, Blood sinuses.

than that of the corpora cavernosa penis. The trabeculae are more delicate, nearly uniform in size, and the meshes between them are smaller than those in the corpora cavernosa penis: their long diameters, for the most part, corresponding with that of the penis. The external envelope or outer coat of the corpus spongiosum is formed partly of unstriped muscular fibers, and a layer of the same tissue immediately surrounds the canal of the urethra. The corpus spongiosum with its expanded end, the glans penis, may be readily dissected away from the corpora cavernosa penis.

Under cerebral or spinal stimuli, the supply of arterial blood to the blood sinuses or interspaces is increased. This increase in

size of sinuses in turn produces compression of the deep veins of the penis due to the elasticity of Buck's fascia. Erection, therefore, is due to mechanical engorgement of the blood sinuses.

**VESSELS AND NERVES.** Most of the blood to the penis is supplied by the internal pudendal artery, a branch of the internal iliac artery. The **arteries** (Fig. 17-49) that supply the cavernous spaces are the deep arteries of the penis and branches from the dorsal arteries of the penis, which perforate the fibrous capsule along the upper surface, especially near the distal end of the organ. On entering the cavernous structure, the arteries divide into branches that are supported and enclosed by the trabeculae. Some of these arteries end in a capillary network, the branches of which open directly into the cavernous spaces. Others assume a tendril-like appearance and form convoluted and somewhat dilated vessels, which are called the **helicine arteries**. They open into the spaces and also give off small capillary branches to supply the trabecular structure. They are bound in the spaces by fine fibrous processes, and are most abundant in the proximal part of the corpora cavernosa (Fig. 17-50).

The blood from the cavernous spaces is returned by a series of **veins** (Figs. 17-50; 17-51), some of which emerge from the base of the glans penis and converge on the dorsum of the organ to form the deep dorsal vein; others pass out on the upper surface of the corpora cavernosa and join the same vein. Some also emerge from the undersurface of the corpora cavernosa penis and, receiving branches from the corpus spongiosum, wind around the sides of the penis to end in the deep dorsal vein, but the greater number pass out at the root of the penis and join the prostatic plexus. Batson (1940) demonstrated that the deep dorsal vein of the penis has a connection with the vertebral veins, hence it is possible for metastases from cancerous involvement of the pelvic viscera or external genitalia to make their way to the vertebrae or even to the skull and brain

**FIG. 17-49.** Diagram of the arteries of the penis. (Testut.)

FIG. 17-50. Transverse section of the penis.

without going through the heart and lungs. Pyogenic organisms may be transported by the same route.

The **lymphatic vessels of the penis** are described in Chapter 10.

The **nerves** are derived from the pudendal nerve and the pelvic plexuses. On the glans and bulb some filaments of the cutaneous nerves have Pacinian bodies connected with them, many of which end in peculiar endbulbs.

FIG. 17-51. Superficial veins of the penis. (Testut.)

## PROSTATE

The **prostate** (Figs. 17-27; 17-28; 17-52) is a firm, partly glandular and partly muscular body placed immediately below the internal urethral orifice and around the commencement of the urethra. It is situated in the pelvic cavity, below the caudal part of the symphysis pubis, cranial to the deep layer of the urogenital diaphragm, and ventral to the rectum, through which it may be distinctly felt, especially when enlarged.

The prostate measures about 4 cm transversely at the base, 2 cm in its anteroposterior diameter, and 3 cm in its vertical diameter. It weighs about 20 gm. It is held in position by the puboprostatic ligaments, by the deep layer of the urogenital diaphragm, which invests the prostate and the commencement of the membranous portion of the urethra, and by the anterior portions of the levatores ani, which pass dorsalward from the pubis and embrace the sides of the prostate. These portions of the levatores ani are named the **levatores prostatae** from the support that they afford to the prostate.

The prostate is perforated by the urethra and the ejaculatory ducts (Fig. 17-43). The urethra usually lies along the junction of its anterior with its middle third. The ejaculatory ducts pass obliquely through the posterior part of the prostate and open into the prostatic portion of the urethra.

## Borders and Surfaces

The prostate presents for examination a **base**, an **apex**, a **posterior**, an **anterior**, and two **lateral surfaces**. The **base** is applied to the caudal surface of the bladder. The greater part of this surface is directly continuous with the bladder wall; the urethra penetrates it nearer its ventral than its dorsal border.

The **apex** is directed caudalward and is in contact with the deep layer of the urogenital diaphragm.

**POSTERIOR SURFACE.** The posterior surface (**dorsal surface**; **rectal surface**) is flattened from side to side and slightly convex craniocaudally; it is separated from the rectum by its sheath and the important rectovesicle (*Denonvilliers*'<sup>1</sup>) fascia, which corre-

<sup>1</sup>Charles Pierre Denonvilliers (1808-1872): A French anatomist and surgeon (Paris).

Fig. 17-52. Prostate with seminal vesicles and seminal ducts, viewed ventrally and cranially. (Spalteholz.)

sponds in origin and fate to the processus vaginalis in the inguinal region. It is about 4 cm distant from the anus.

Near its cranial border is a depression through which the two ejaculatory ducts enter the prostate. This depression divides the posterior surface into a lower larger and an upper smaller part. The cranial smaller part constitutes the **middle lobe** of the prostate and intervenes between the ejaculatory ducts and the urethra; it varies greatly in size, and in some cases is destitute of glandular tissue. The caudal larger portion sometimes has a shallow median furrow, which imperfectly separates it into a **right** and a **left lateral lobe**. These form the main mass of the gland and are directly continuous with each other dorsal to the urethra. Cranial to the urethra the lobes are connected by a band named the **isthmus**, which consists of the same tissues as the capsule and is devoid of glandular substance.

**ANTERIOR SURFACE.** The anterior surface (ventral surface; pubic surface) measures about 2.5 cm craniocaudally but it is narrow and convex from side to side. It is placed about 2 cm dorsal to the pubic symphysis, from which it is separated by a plexus of veins and a quantity of loose fat. It is connected to the pubic bone on either side by the **puboprostatic ligaments**. The urethra emerges from this surface a little cranial and ventral to the apex of the gland.

**LATERAL SURFACES.** The lateral surfaces are prominent and are covered by the ventral portions of the levatores ani which, however, are separated from the gland by a plexus of veins.

### Structure

The prostate is immediately enveloped by a thin but firm fibrous capsule distinct from that derived from the subserous fascia and separated from it by a plexus of veins. This capsule adheres firmly to the prostate and is structurally continuous with the stroma of the gland, being composed of the same tissues: nonstriated muscle and fibrous tissue. The substance of the prostate is dense, a pale reddish-gray, and not easily torn. It consists of glandular substance and muscular tissue (Fig. 17-53).

The **muscular tissue** constitutes the proper stroma of the prostate; the connective tissue being scanty and simply forming, between the muscular fibers, thin trabeculae in which the vessels and nerves of the gland ramify. The muscular tissue is arranged as follows: immediately beneath the fibrous capsule is a dense layer that forms an investing sheath for the gland; around the urethra, as it lies in the prostate, is another dense layer of circular fibers that is continuous above with the internal layer of the muscular coat of the bladder and blends below

**FIG. 17-53.** Section through prostate of a 22-year-old man. c.t., Connective tissue stroma; ep., glandular epithelium; gl., lumen of gland; m., smooth muscle fiber in stroma. 50  $\times$ . (Sobotta.)

with the fibers surrounding the membranous portion of the urethra. Between these two layers, strong bands of muscular tissue, which decussate freely, form meshes in which the glandular structure of the organ is embedded. In the part of the gland that is situated in front of the urethra the muscular tissue is especially dense, and there is little or no gland tissue, while in the part that is behind the urethra, the muscular tissue presents a wide-meshed structure, which is densest at the base of the gland (i.e., near the bladder) and becomes looser and more sponge-like toward the apex of the organ.

The **glandular substance** is composed of numerous follicular pouches, the lining of which frequently shows papillary elevations. The follicles open into elongated canals that join to form 12 to 20 small excretory ducts. They are connected by areolar tissue, supported by prolongations from the fibrous capsule and muscular stroma, and enclosed in a delicate capillary plexus. The epithelium that lines the canals and the terminal vesicles is columnar. The prostatic ducts open into the floor of the prostatic portion of the urethra and are lined with two layers of epithelium, the inner layer consist-

ing of columnar and the outer of small cubical cells. Small colloid masses, known as **amyloid bodies**, are often found in the gland tubes.

**VESSELS AND NERVES.** The arteries supplying the prostate are derived from the internal pudendal, inferior vesical, and middle rectal arteries. Its veins form the prostatic plexus, which surrounds the sides and base of the gland. The plexus receives the dorsal vein of the penis and empties into the internal iliac veins. It has anastomotic connections with the vertebral system of veins, through which metastases of carcinoma may reach the bones or even the brain. The **lymphatics** are described in Chapter 10.

The **nerves** are derived from the pelvic plexus.

### BULBOURETHRAL GLANDS

The **bulbourethral glands** (Cowper's glands) (Fig. 17-27) are two small, round, and somewhat lobulated yellow bodies, about the size of peas, placed dorsal and lateral to the membranous portion of the urethra between the two layers of the fascia of the urogenital diaphragm. They lie close to the bulb and are enclosed by the transverse fibers of the sphincter urethrae.

The excretory duct of each gland, nearly 2.5 cm long, passes obliquely forward beneath the mucous membrane and opens by a minute orifice on the floor of the cavernous portion of the urethra about 2.5 cm in front of the urogenital diaphragm.

#### Structure

Each gland is made up of several lobules held together by a fibrous investment. Each lobule consists of acini, lined by columnar epithelial cells, opening into one duct, which joins with the ducts of other lobules outside the gland to form the single excretory duct.

## Female Genital Organs

The **female genital organs** consist of an internal and an external group. The **internal organs** are situated within the pelvis and consist of the **ovaries**, the **uterine tubes**, the **uterus**, and the **vagina**. The **external organs** are superficial to the urogenital diaphragm and below the pubic arch. They comprise the **mons pubis**, the **labia majora** and **minora pudendi**, the **clitoris**, the **vestibule**, the **bulb of the vestibule**, and the **greater vestibular glands**.

## OVARIES

The **ovaries** are homologous with the testes in the male. They are two nodular bodies, situated one on either side of the uterus in relation to the lateral wall of the pelvis and attached to the broad ligament of the uterus, dorsal and caudal to the uterine tubes (Fig. 17-54). The ovaries are grayish-pink and have either a smooth or a puckered, uneven surface. They are each about 4 cm long, 2 cm wide, and about 8 mm thick, and weigh 2 to 3.5 gm. Each ovary has a lateral and a medial surface, a cranial or tubal and a caudal or uterine extremity, and a ventral or mesovarian and a dorsal free border. It lies in a shallow depression, named the **ovarian fossa**, on the lateral wall of the pelvis; this fossa is bounded by the external iliac vessels, the obliterated umbilical artery, and the ureter. The exact position of the ovary has been the subject of considerable differences of opinion, and the description given here refers to the ovary of the nulliparous woman. The ovary becomes displaced during the first pregnancy and probably never again returns to its original position. In the erect posture the long axis of the ovary is vertical.

The **tubal extremity** is near the external iliac vein. Attached to it are the ovarian fimbriae of the uterine tube and a fold of peritoneum, the **suspensory ligament of the**

**ovary**, which is directed cranialward over the iliac vessels and contains the ovarian vessels. The **uterine end** is directed caudalward toward the pelvic floor; it is usually narrower than the tubal end and is attached to the lateral angle of the uterus, immediately behind the uterine tube, by a round cord termed the **ligament of the ovary**, which lies within the broad ligament and contains some nonstriated muscular fibers.

The **lateral surface** is in contact with the parietal peritoneum, which lines the ovarian fossa; the **medial surface** is covered largely by the fimbriated extremity of the uterine tube. The **mesovarian border** is straight and directed toward the obliterated umbilical artery; it is attached to the dorsal surface of the broad ligament by a short fold named the **mesovarium**. Between the two layers of this fold, the blood vessels and nerves pass to the hilum of the ovary. The **free border** is convex and directed toward the ureter. The uterine tube arches over the ovary, runs along its mesovarian border, then curves over its tubal pole and finally passes along its free border and medial surface.

## Epoöphoron

The **epoöphoron** (parovarium; organ of Rosenmüller) (Fig. 17-55) lies in the mesosalpinx between the ovary and the uterine tube, and consists of a few short tubules (**ductuli**

**Fig. 17-54.** Uterus and right broad ligament, seen dorsally. The broad ligament has been spread out and the ovary drawn caudalward.

**FIG. 17-55.** Broad ligaments of adult, showing remains of the Wolffian body and duct. (Modified from Farre.)

*transversi*), which converge toward the ovary while their opposite ends open into a rudimentary duct, the **ductus longitudinalis epoöphori** (duct of Gartner).

### **Paroöphoron**

The paroöphoron consists of a few scattered rudimentary tubules, best seen in the child, situated in the broad ligament between the epoöphoron and the uterus. The ductuli transversi of the epoöphoron and the tubules of the paroöphoron are remnants of the tubules of the Wolffian body or mesonephros; the ductus longitudinalis epoöphori is a persistent portion of the mesonephric or Wolffian duct. In the fetus the ovaries are situated, like the testes, in the lumbar region, near the kidneys, but they gradually descend into the pelvis.

### **Structure**

The surface of the ovary is covered by a layer of columnar cells, which constitutes the **germinal epithelium** (of Waldeyer<sup>1</sup>). This

epithelium, which is in linear continuity with the peritoneum, gives to the ovary a dull gray color compared with the shining smoothness of the peritoneum, and the transition between the squamous epithelium of the peritoneum and the columnar cells that cover the ovary is marked by a line near the attached border of the ovary. The ovary consists of a number of vesicular ovarian follicles embedded in the meshes of a stroma or framework (Fig. 17-56).

**STROMA.** The stroma is a peculiar soft tissue consisting mostly of spindle-shaped cells with a small amount of ordinary connective tissue abundantly supplied with blood vessels. At the surface of the organ, this tissue is much condensed and forms a layer (**tunica albuginea**) composed of short connective tissue fibers, with fusiform cells between them.

**OVARIAN FOLLICLES.** The stroma immediately beneath the tunica albuginea, containing a large number of minute vesicles about 35  $\mu$ m in diameter, constitutes the **cortex** of the ovary. These vesicles are the **primary follicles** (Fig. 17-56). They contain an ovum about 20  $\mu$ m in diameter surrounded by a single layer of follicular cells. When these follicles begin to mature, the ovum swells and the follicular cells become larger and

<sup>1</sup>Heinrich Wilhelm Gottfried Waldeyer (1836-1921): A German anatomist (Breslau and Berlin).

**FIG. 17-56.** Section through ovary of 23-year-old woman. Lightly stained with hematoxylin. 5  $\times$ .

proliferate by mitosis. When the follicular cells form many layers, a cavity filled with fluid forms at one side. This is the beginning of **vesicular** or **ripening follicles**. These recede from the surface toward the highly vascular stroma in the center of the organ, termed the **medullary substance** (*zona vasculosa* of *Waldeyer*). This stroma forms the tissue of the hilum by which the ovary is attached and through which the blood vessels enter; it does not contain follicles.

When the follicle is mature, it forms a clear vesicle 10 to 12 mm in diameter and is known as a **Graafian<sup>1</sup> follicle**. The follicular cells are arranged in a layer three or four cells thick around the large accumulation of follicular fluid. At one side of the follicle they form a mass of cells protruding into the cavity, constituting the **cumulus oophorus**. The ovum, now about 100  $\mu$ m in diameter, is in the center of the cumulus, with the layer of follicular cells immediately surrounding

arranged in a regular row known as the **corona radiata**.

**THECA FOLLICULI.** During the stages of growth of the follicle, the cells of the stroma around it become flattened into a sheath or theca (Fig. 17-57). When the follicle is ma-

**FIG. 17-57.** Section of a vesicular ovarian follicle. 50  $\times$ .

<sup>1</sup>Reijnier de Graaf (1641-1673): A Dutch physician and anatomist (Delft).

ture, the theca develops an outer and inner stratum, the **theca interna** and **theca externa**.

**OVULATION.** The mature follicle presses against the tunica albuginea, thinning it and bulging out on the surface of the ovary. Under the influence of hormones of the hypophysis, the follicle ruptures, allowing the fluid to escape into the abdominal cavity and the ovum to be swept into the fimbriated opening of the uterine tube. The cavity of the follicle collapses but contains some fluid tinged with blood, which gives it the name **corpus hemorrhagicum** (Fig. 17-56). The remaining follicular cells become greatly enlarged and take on a yellow color, forming the **corpus luteum**. The cells of the theca interna also enlarge, forming **theca lutein cells** in contrast to the **follicular lutein cells**. If the ovum is fertilized, the corpus luteum continues to grow, attaining a size of 30 mm by the end of nine months. This is a **corpus luteum graviditatis**.

When the ovum is not fertilized, the follicle forms a much smaller **corpus luteum menstruationis**. After the corpus degenerates, the connective tissue forms a folded whitish scar known as a **corpus albicans** (Fig. 17-56).

The periodic changes in the ovary and uterus during the menstrual cycle are discussed later.

**ATRESIA OF FOLLICLES.** Many of the follicles do not reach full maturity and rupture; they undergo instead a degenerative process known as atresia. In smaller follicles, the ovum disintegrates and is absorbed with the degenerating follicular cells. With large follicles, after the follicular cells degenerate, the theca cells form a layer around the follicle and are absorbed into the stroma.

**VESSELS AND NERVES.** The **arteries** of the ovaries and uterine tubes are the ovarian from the aorta. Each anastomoses freely in the mesosalpinx, with the uterine artery giving off some branches to the uterine tube and others that traverse the mesovarium and enter the hilum of the ovary. The **veins** emerge from the hilum in the form of a plexus, the **pampiniform plexus**; the ovarian vein is formed from this plexus, and leaves the pelvis in company with the artery. The **lymphatics** are described in Chapter 10. The **nerves** are derived from the hypogastric or pelvic plexus and from the ovarian plexus; the uterine tube receives a branch from one of the uterine nerves.

## UTERINE TUBE

The uterine tubes (*Fallopian tube*<sup>1</sup>; oviduct) (Figs. 17-58; 17-59; 17-61) convey the ova from the ovaries to the cavity of the uterus. They are bilateral, extending from the superior lateral angle of the uterus to the side of the pelvis. Each one is suspended by a mesenteric peritoneal fold called the **mesosalpinx**, which comprises the upper free margin and adjacent movable portion of the broad ligament. Each tube is about 10 cm long and consists of three portions: (1) the **isthmus**, or medial constricted third; (2) the **ampulla**, or intermediate dilated portion, which curves over the ovary; and (3) the **infundibulum** with its **abdominal ostium**, surrounded by **fimbriae**, one of which, the **ovarian fimbria**, is attached to the ovary. The uterine tube is directed lateralward as far as the uterine pole of the ovary, and then ascends along the mesovarian border of the ovary to the tubal pole, over which it arches; finally it turns downward and ends in relation to the free border and medial surface of the ovary. The uterine opening is minute and admits only a fine bristle; the abdominal opening is somewhat larger. Frequently one or more small pedunculated vesicles are connected with the fimbriae of the uterine tube or with the broad ligament close to them. These are termed the **appendices vesiculosae** (hydatids of Morgagni).

### Structure

The uterine tube consists of three coats: **serous**, **muscular**, and **mucous**. The **external** or **serous coat** is peritoneal. The **middle** or **muscular coat** consists of an external longitudinal and an internal circular layer of nonstriated muscular fibers continuous with those of the uterus. The **internal** or **mucous coat** is continuous with the mucous lining of the uterus, and at the abdominal ostium of the tube, with the peritoneum. It is thrown into longitudinal folds, **plicae tubariae**, which are much more extensive in the ampulla than in the isthmus. The lining epithelium is columnar and ciliated. This form of epithelium is also found on the inner surface of the fimbriae, while on the outer or serous

<sup>1</sup>Gabriele Fallopio (1523–1562): An Italian anatomist and student of Vesalius (Padua).

**FIG. 17-58.** Female pelvis and its contents, seen from above and in front.

surfaces of these processes the epithelium merges into the mesothelium of the peritoneum.

Fertilization of the ovum is believed to occur in the tube (see Chapter 2), and the fertilized ovum then normally passes into the uterus. The ovum, however, may adhere to and develop in the uterine tube, giving rise to the commonest variety of ectopic gestation. In such cases the amnion and chorion are formed, but a true decidua is never present. The gestation usually ends by extrusion of the ovum through the abdominal ostium, although the tube may rupture into the peritoneal cavity; this is accompanied by severe hemorrhage and requires surgical intervention.

**VESSELS AND NERVES.** The **arteries** that supply the uterine tube are branches of the uterine and ovarian arteries. One branch from the uterine artery, much stronger than the others, has special surgical importance (Sampson's<sup>1</sup> artery). It arises just before the uterine artery anastomoses with the ovarian artery, and continues along the tube to its fimbriated extremity, giving off branches along its course. The **veins** drain into the uterine plexus. The **lymphatics**

drain partly with the uterine and partly with the ovarian vessels.

The **nerves** are derived from the pelvic plexus of sympathetic and parasympathetic sacral nerves.

## THE UTERUS

The **uterus** (womb) (Figs. 17-54; 17-58 to 17-60) is a thick-walled, hollow, muscular organ situated in the pelvis between the bladder and the rectum. The uterine tubes open into its upper abdominal part, and at its perineal end its cavity communicates with that of the vagina. It changes remarkably in size, structure, and position during pregnancy, and although it returns again almost to its former condition, the following description is based on the uterus of an adult woman who has never been pregnant.

The uterus is pear-shaped, somewhat flattened dorsoventrally, and elongated, with its long axis parallel with the median plane but curved to correspond with the axis of the pelvis. It measures about 7.5 cm in length, 5 cm in breadth at its cranial part, and nearly 2.75 cm in thickness; it weighs 30 to 40 gm.

The uterus is divided structurally and functionally into two parts, the body and the cervix. On the surface, about midway be-

<sup>1</sup>John Albertson Sampson (1873-1943): An American gynecologist (Albany).

**FIG. 17-59.** Median sagittal section of female pelvis. The bladder is empty; the uterus and vagina are slightly dilated. (Eycleshymer and Jones.)

tween the two ends, is a slight constriction known as the **isthmus**. Corresponding to this on the inside is a narrowing of the cavity, formerly known as the **internal orifice** of the uterus. The part cranial to the isthmus is the body; caudal to it, the cervix.

### Body

The part of the body (*corpus uteri*) that extends toward the abdomen as a free, rounded extremity above the entrance of the uterine tubes is called the **fundus**. The body gradually narrows from the fundus to the isthmus (Fig. 17-61).

The ventral or **vesical surface** faces toward the bladder, and the peritoneum covering its surface is reflected, at the junction with the cervix, into the vesicouterine excavation and thence to the bladder.

The dorsal or **intestinal surface** is more

convex and the peritoneum covering its surface is more extensive than that of the vesical surface. It extends over the cervix and over the cranial portion of the vagina. The peritoneal excavation between it and the rectum is the rectouterine fossa and is usually occupied by coils of small intestine.

The **fundus** is convex in all directions and its free surface, covered by peritoneum, is usually in contact with coils of small intestine or a distended sigmoid colon.

The **lateral margins** are slightly convex. At the upper end of each, the uterine tube joins the uterine wall. Ventral and caudal to this point the **round ligament of the uterus** is fixed, while dorsal to it is the attachment of the **ligament of the ovary**. These three structures lie within a fold of peritoneum that is reflected from the margin of the uterus to the wall of the pelvis, and is named the **broad ligament**.

**FIG. 17-60.** Genital tract in the female after an injection of barium sulfate into the uterus. X, Body of uterus. Note the two cornua leading to the uterine tubes. X X, Speculum in vagina. The arrows indicate the infundibula of the uterine tubes. Some of the barium has passed through the pelvic opening of the tube into the general peritoneal cavity.

### **Cervix**

The cervix (neck) is the portion of the uterus between the isthmus and the vagina. It is about 2 cm long, and the end toward the perineum protrudes into the cavity of the vagina as a free extremity. The attachment of the vagina around its periphery divides it into a vaginal and a supravaginal portion.

The **supravaginal portion** is separated ventrally from the bladder by fibrous tissue (**parametrium**), which extends also to its sides and lateralward between the layers of the broad ligaments. The uterine arteries reach the margins of the cervix in this fibrous tissue, where they cross over the ureters. The ureters, on either side, run ventralward in the parametrium about 2 cm from the cervix. Dorsally, the supravaginal cervix is covered by peritoneum, which is prolonged caudalward on the posterior vaginal wall before it is reflected over to the rectum.

The **vaginal portion** of the cervix projects into the cavity of the vagina, the free end

resting against the dorsal wall. On its rounded extremity is a round or oval depression that marks the **uterine orifice** (external os) leading into the cavity of the cervix. The orifice is bounded by two lips, the **ventral lip** and the **dorsal lip**. Between the dorsal lip and the vaginal wall is the **posterior fornix**, the most cranial part of the vaginal cavity, and between the ventral lip and the vaginal wall is the **anterior fornix** (Fig. 17-59).

The **cavity of the uterus** is compressed dorsoventrally into a mere slit. The orifices of the uterine tubes and the internal surface of the fundus form the base of a triangle whose apex is the isthmus, leading into the canal of the cervix. The total length of the uterine cavity from the external orifice to the fundus is about 6.25 cm.

### **Canal of Cervix**

The canal of the cervix (Fig. 17-61) is somewhat flattened and wider in the middle than at either extremity. It communicates

Fig. 17-61. Section through the vagina, uterus, uterine tube, and ovary.

through the isthmus with the cavity of the uterine body, and through the external orifice with the vaginal cavity. The wall of the canal has an anterior and a posterior longitudinal ridge, from each of which proceed a number of small oblique columns, the **pal-mate folds**, which give the appearance of branches from the stem of a tree. To this arrangement, the name **arbor vitae uterina** is applied. The folds on the two walls are not opposed exactly, but fit between one another to close the cervical canal.

### Ligaments

The principal ligaments of the uterus are the **broad ligaments**, the **round ligaments**, the **uterosacral ligaments**, and the **cardinal ligaments**. In addition, certain peritoneal folds are called ligaments: the **vesicouterine**, **rectouterine**, and **sacrogenital ligaments**.

**BROAD LIGAMENTS.** The broad ligaments (Figs. 17-54; 17-55) are two fibrous sheets, cov-

ered on both surfaces with peritoneum, that extend from each side of the uterus to the lateral wall and bottom of the pelvis. The uterus and these lateral extensions together form a septum across the cavity of the pelvis, dividing it into a **vesicouterine** and a **rectouterine fossa** (Figs. 17-58; 17-59, not labeled). The broad ligament is thicker at its inferior pelvic attachment than at its free border. Between the two peritoneal sheets or *leaves* of the ligament are:

1. Parametrium
2. Uterine artery
3. Uterine tube
4. Round ligament
5. Epoöphoron and paroöphoron
6. (Ovary)
7. (Ureter)

1. The **parametrium** is the extension of the subserous connective tissue of the uterus laterally into the broad ligament. The name has been applied also to the whole broad lig-

ament below the attachment of the ovary, but sometimes the latter is referred to as the **mesometrium**. It contains scattered smooth muscle bundles, is anchored to the lateral pelvic wall, and is continuous with the cardinal ligament of the intrapelvic fascia.

2. The **uterine artery** of each side enters the base of the broad ligament at the latter's attachment to the lateral wall of the pelvis and traverses the pelvis between the two leaves close to their reflection to the pelvic floor. It crosses the ureter just before it reaches the cervical portion of the uterus, and in the parametrium it follows the lateral border of the uterus up to the isthmus of the uterine tube. It follows the tube laterally and anastomoses with the ovarian artery. The **ovarian artery** crosses the external iliac vessels in a vertical direction, enters the most superior lateral portion of the broad ligament enclosed in a fibrous cord, the **suspensory ligament of the ovary** (*infundibulopelvic ligament*), and follows the attached border of the ovary to the anastomoses with the uterine artery.

3. The superior free border of the broad ligament is occupied by the **uterine tube**, except at its lateral extremity, where it forms the suspensory ligament of the ovary which also attaches the infundibulum of the tube to the lateral wall of the pelvis. The free portion of the broad ligament extending down as far as the attachment of the ovary is called the **mesosalpinx**. It is less fixed than the rest of the ligament and affords a movable mesenteric support for the tube.

4. The **round ligaments** are described below with the other ligaments of the uterus.

5. The **epoöphoron** and **paroöphoron** lie in the mesosalpinx.

6. The **ovary** is secured to the posterior surface of the broad ligament by a mesenteric attachment, the **mesovarium**, derived from the posterior leaf. It does not lie, therefore, between the leaves of the broad ligament. Folds of the posterior leaf at each end of the ovary cover the suspensory ligament of the ovary and the **ligamentum ovarii proprium**, a musculo-fibrous cord joining the ovary to the uterus.

7. The **ureter** crosses the attached inferior border of the broad ligament obliquely, as it courses along the pelvic floor toward the base of the bladder. It comes to within 1 or 2 cm of the uterus at this point and lies close to the uterine artery, between the latter and the pelvic diaphragm.

**ROUND LIGAMENT.** The round ligament is a flat band attached to the superior part of the lateral border of the uterus just caudal and ventral to the isthmus of the uterine tube. It traverses the pelvis between the leaves of the broad ligament but causes a prominent protrusion of the anterior leaf only. It reaches the pelvic wall lateral to the lateral vesicocumbilical fold, ascends over the external iliac vessels and inguinal ligament, and penetrates the abdominal wall through the deep inguinal ring. It passes through the inguinal canal, and its constituent fibers spread out to help form the substance of the labia majora. In the fetus, the peritoneum is prolonged in the form of a tubular process for a short distance into the inguinal canal beside the ligament. This process is called the **canal of Nuck** (Fig. 17-62). It is generally obliterated in the adult, but sometimes remains pervious even in advanced life. It is analogous to the saccus vaginalis, which precedes the descent of the testis.

**CARDINAL LIGAMENT.** The cardinal ligament (of Mackenrodt<sup>1</sup>) is a fibrous sheet of the subserous fascia embedded in the adipose tissue on each side of the lower cervix uteri and vagina. To form it, the fasciae over the ventral and dorsal walls of the vagina and cervix come together at the lateral border of these organs, and the resulting sheet extends across the pelvic floor as a deeper

<sup>1</sup>Alwin Mackenrodt (1859-1925): A German gynecologist and pathologist (Berlin).

FIG. 17-62. Sagittal section through the pelvis of a newly born female child.

continuation of the broad ligament. As the sheet reaches the lateral portion of the pelvic diaphragm, it forms ventral and dorsal extensions that are attached to the internal investing layer of deep fascia (supra-anal fascia) on the inner surface of the levator ani, coccygeus and piriformis muscles. This attachment is commonly visible as a white line 2 or 3 cm below the arcus tendineus of the levator ani, and is called the **arcus tendineus of the pelvic fascia**. The ventral extension is continuous with the tissue supporting the bladder; the dorsal extension blends with the uterosacral ligaments. The vaginal arteries cross the pelvis in close association with this ligament, giving it additional substance and support, and bundles of smooth muscle may be embedded in it.

**UTEROSACRAL LIGAMENT.** The uterosacral ligament is a prominent fibrous band of subserous fascia that takes a curved course along the lateral wall of the pelvis from the cervix uteri to the sacrum. It is a posterior continuation of the tissue that forms the cardinal ligament. It is attached to the deep fascia and periosteum of the sacrum and contains a bundle of smooth muscle named the **rectouterinus**. The ligaments on the two sides project out from the wall as crescentic shelves, which narrow the diameter of the cavity ventral to the lower rectum and mark it off as the *cul-de-sac of Douglas*.<sup>1</sup>

**OTHER LIGAMENTS AND FOLDS.** The **vesicouterine fold** or **anterior ligament** is the reflection of peritoneum from the anterior surface of the uterus, at the junction of the cervix and body, to the posterior surface of the bladder.

The **rectovaginal fold** or **posterior ligament** is the peritoneum reflected from the wall of the posterior fornix of the vagina onto the anterior surface of the rectum.

The **sacrogenital** or **rectouterine folds** (of Douglas) are two crescentic folds that cover the uterosacral ligaments.

The **rectouterine excavation** (pouch or *cul-de-sac of Douglas*) is a deep pouch formed by the most inferior or caudal portion of the parietal peritoneum. Its ventral boundary is the supravaginal cervix and posterior fornix of the vagina; dorsal boundary, the rectum; and lateral boundary, the sacrogenital folds covering the uterosacral ligaments.

<sup>1</sup>James Douglas (1675-1742): An English physician and anatomist (London).

### **Support of the Uterus**

The principal support of the uterus is the pelvic diaphragm, especially the levator ani and its investing layers of fascia, and unless it is intact the other structures are unable to carry out their supporting function. The uterus is held in its proper position within the pelvis by its attachment to the vagina and by the cardinal, broad, and uterosacral ligaments. The blood vessels reinforce these ligaments. The round ligaments and the peritoneal folds have relatively slight importance as mechanical supports. The padding of adipose tissue about the ligaments and organs, in well-nourished individuals, is an important element of support. There is a great variation in the size and development of the supporting structures in different individuals, and they may be thickened or strengthened in response to physiologic and pathologic changes.

### **Position of the Uterus**

The form, size, and situation of the uterus vary at different periods of life and under different circumstances.

In the *fetus and infant*, the uterus is contained in the abdominal cavity, projecting beyond the superior aperture of the pelvis (Fig. 17-62). The cervix is considerably larger than the body.

At puberty, the uterus is piriform and weighs 14 to 17 gm. It has descended into the pelvis, the fundus being just below the level of the superior aperture of this cavity. The palmate folds are distinct and extend to the upper part of the cavity of the organ.

The position of the uterus in the *adult* is liable to considerable variation. With the bladder and rectum empty, the body of the uterus is nearly horizontal when the individual is standing. The fundus is about 2 cm behind the symphysis pubis and slightly cranial to it. The uterus and vagina are at an angle of about 90° with each other. The external os is half way between the spines of the ischia. As the bladder fills, the uterus is bent back toward the sacrum.

During menstruation, the organ is enlarged, more vascular, and its surfaces rounder; the external orifice is rounded, its labia swollen, and the lining membrane of the body thickened, softer, and darker.

During pregnancy, the uterus becomes enormously enlarged, and in the eighth

month reaches the epigastric region. The increase in size is partly due to growth of preexisting muscle and partly to the development of new fibers.

After parturition, the uterus nearly regains its usual size, weighing about 42 gm, but its cavity is larger than in the virgin state; its vessels are tortuous, and its muscular layers are more defined; the external orifice is more marked, and its edges present one or more fissures.

In old age, the uterus becomes atrophied, paler, and denser in texture; a more distinct constriction separates the body and cervix. The isthmus is frequently, and the ostium occasionally, obliterated, while the lips almost entirely disappear.

### Structure

The uterus is composed of three coats: an **external** or **serous**, a **middle** or **muscular**, and an **internal** or **mucous coat**.

**SEROUS COAT.** The serous coat (perimetrium) is derived from the peritoneum; it invests the fundus and the whole of the intestinal surface of the uterus, but covers the vesical surface only as far as the junction of the body and cervix. In the lower fourth of the intestinal surface, the peritoneum, though covering the uterus, is not closely connected with it, being separated from it by a layer of loose cellular tissue and some large veins.

**MUSCULAR COAT.** The muscular coat (myometrium) forms the chief bulk of the substance of the uterus. In the non-gravid young woman it is dense, firm, and grayish, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the uterine tubes. It consists of bundles of unstriated muscular fibers disposed in a thick, felt-like structure, intermixed with areolar tissue, blood vessels, lymphatic vessels, and nerves. Muscle fibers are continued on to the uterine tube, the round ligament, and the ligament of the ovary, some passing at each side into the broad ligament, and others running backward from the cervix into the uterosacral ligaments. During pregnancy the muscular tissue becomes more prominently developed, the fibers being greatly enlarged.

**MUCOUS MEMBRANE.** The mucous membrane (endometrium) (Fig. 17-63) is smooth and closely adherent to the subjacent muscular tissue. It is continuous through the fim-

**Fig. 17-63.** Vertical section of mucous membrane of human uterus. ep., epithelium; gl., lumen of gland; m., muscularis; s., connective tissue stroma. (Sobotta.)

bricated extremity of the uterine tubes with the peritoneum, and through the uterine ostium with the lining of the vagina.

In the *body* of the uterus, the mucous membrane is smooth, soft, pale red, lined by a single layer of high columnar ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular follicles arranged perpendicularly to the surface. The structure of the corium differs from that of ordinary mucous membranes; it consists of an embryonic nucleated and highly cellular form of connective tissue containing numerous large lymphatics. In it are the tube-like **uterine glands**.

In the *cervix*, the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous oblique ridges that diverge from an anterior and posterior longitudinal raphe. In the upper two-thirds of the canal, the mucous membrane is provided with numerous deep glandular follicles that secrete a clear viscid alkaline mucus; in addition, extending through the whole length of the canal is a variable number of little cysts that have become occluded and distended with retained secretion. These are called the **ovula Nabothi**.<sup>1</sup> The mucous membrane covering the lower half of the cervical canal has numerous papillae. The epithelium of the upper two-thirds is cylindrical and ciliated, but below

<sup>1</sup>Martin Naboth (1675-1721): A German anatomist (Leipzig).

this it loses its cilia and gradually changes to stratified squamous epithelium close to the ostium uteri. On the vaginal surface of the cervix the epithelium is stratified squamous similar to that lining the vagina.

**VESSELS AND NERVES.** The **arteries** of the uterus are the uterine, from the internal iliac artery, and the ovarian, from the abdominal aorta. They are remarkable for their tortuous course in the substance of the organ and for their frequent anastomoses. The termination of the ovarian artery meets that of the uterine artery and forms an anastomotic trunk from which branches are given off to supply the uterus in a circular disposition.

The **veins** are large and correspond with the arteries. They end in the uterine plexuses. In the impregnated uterus, the arteries carry the blood to, and the veins convey it away from, the intervillous space of the placenta. The **lymphatics** are described in Chapter 10.

The **nerves** are derived from the hypogastric and ovarian plexuses and from the third and fourth sacral nerve. Afferent fibers from the uterus enter the spinal cord solely through the eleventh and twelfth thoracic nerves.

### Menstrual Cycle

After puberty and throughout the child-bearing period the endometrium undergoes periodic changes called the **menses**. The manifestation of this cycle is bleeding from the uterus, and the beginning of the bleeding is used as the point of time from which the cycle is measured. The common length of a cycle is 28 days, but this may vary markedly from individual to individual and between cycles of the same individual.

The changes in the uterus are closely correlated with cyclic changes in the ovary, and the two organs must be considered together. Although the changes are a continuous process, the cycle is usually divided into four phases: (a) proliferative, (b) secretory or prograavid, (c) premenstrual, and (d) menstrual.

**PROLIFERATIVE PHASE.** The portion of the endometrium adjacent to the myometrium, known as the *basalis*, remains after the menstrual flow, allowing the glands and lining epithelium to be restored to an inactive condition such as that shown in Figure 17-63. After the cessation of the menstrual flow, a hormone from the adenohypophysis, the **follicle-stimulating hormone**, causes the growth of one of the ovarian follicles. As the follicle enlarges it produces the hormone **es-**

**trogen**, which stimulates the proliferation of the endometrium, greatly enlarging the uterine glands.

**SECRETORY OR PROGRAVID PHASE.** When the ovarian follicle has ripened into a mature Graafian follicle, it ruptures, frequently at the middle of the cycle, liberating the ovum. The ruptured follicle, under the influence of the pituitary **luteinizing hormone**, develops into a corpus luteum, whose proliferating cells produce the hormone **progesterone**. The progesterone stimulates the enlarged endometrial glands to secrete and prepare the uterus for the reception of the fertilized ovum.

**PREMENSTRUAL PHASE.** If the ovum is fertilized, the corpus luteum continues to grow into the corpus luteum of pregnancy, but if the ovum is not fertilized, the corpus luteum begins to degenerate and it no longer produces hormones. The endometrium responds with changes in the blood supply, deterioration of the tissues, and fragmentation of the glands and epithelium.

**MENSTRUAL PHASE.** That portion of the endometrium containing the enlarged glands and abundant capillaries is known as the *functionalis*, in distinction from the depths of the glands and tissue adjacent to the myometrium, known as the *basalis*. During the menstrual discharge, the functionalis sloughs away and the ruptured vessels produce the *bleeding* of the menstrual flow. The basalis remains to establish the new endometrium for the next succeeding cycle.

### THE VAGINA

The **vagina** (Figs. 17-61; 17-64) extends from the vestibule to the uterus and is situated dorsal to the bladder and ventral to the rectum. Its axis forms an angle of over 90° with that of the uterus. Its walls are ordinarily in contact, and the usual shape of its lower part on transverse section is that of an H, the transverse limb being slightly curved forward or backward, while the lateral limbs are somewhat convex toward the median line; its middle part has the appearance of a transverse slit. The length of the vagina is 6 to 7.5 cm along the ventral wall and 9 cm along the dorsal wall. It is constricted at its commencement, dilated in the middle, and narrowed near its uterine extremity; it surrounds the vaginal portion of the cervix

uteri, its attachment extending higher up on the dorsal than on the ventral wall of the uterus. The recess dorsal to the cervix is the **posterior fornix**; the smaller ventral and lateral recesses are called the **anterior** and **lateral fornices**.

**RELATIONS.** The **ventral surface** of the vagina is in relation with the fundus of the bladder and with the urethra. Its **dorsal surface** is separated from the rectum by the rectouterine excavation in its upper fourth and by the rectovaginal fascia in its middle two-fourths; the lower fourth is separated from the anal canal by the perineal body. As the terminal portions of the ureters pass ventralward and medialward to reach the fundus of the bladder, they run close to the lateral fornices of the vagina, and as they enter the bladder they are slightly in front of the ventral fornix.

### Structure

The vagina consists of an **internal mucous lining** and a **muscular coat** separated by a layer of erectile tissue.

**MUCOUS MEMBRANE.** The mucous membrane is continuous above with that lining the uterus. Its inner surface has two longitudinal ridges, one on its anterior and one on its posterior wall. These ridges are called the **columns of the vagina** and from them numerous transverse ridges or rugae extend outward on either side. These rugae are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillae; they are most numerous near the orifice of the vagina, especially before parturition. The epithelium covering the mucous membrane is of the stratified squamous variety. The submucous tissue is loose and contains a plexus of large veins, together with smooth muscular fibers derived from the muscular coat. It contains mucous crypts, but no true glands.

**MUSCULAR COAT.** The muscular coat consists of two layers: an external longitudinal layer, which is by far the stronger, and an internal circular layer. The longitudinal fibers are continuous with the superficial muscular fibers of the uterus. The strongest fasciculi are those attached to the rectovesical fascia on either side. The two layers are not distinctly separable from each other, but are connected by oblique decussating fasciculi, which pass from the one layer to the other. In addition to this, the vagina at its

lower end is surrounded by the erectile tissue of the bulb of the vestibule and a band of striped muscular fibers, the **bulbospongiosus muscle**.

External to the muscular coat is a layer of connective tissue containing a large plexus of blood vessels.

**VESSELS AND NERVES.** The **vaginal artery** arises from the uterine artery or from the adjacent internal iliac artery, supplies the mucous membrane, and anastomoses with the uterine, inferior vesicle, and middle rectal arteries. The branch of the uterine artery to the cervix descends on the dorsal or ventral wall, forming the azygos artery of the vagina, which anastomoses with the vaginal artery. The **veins** run along both sides, forming plexuses with the uterine, vesical, and rectal veins, and ending in a vein that opens into the internal iliac vein. The **lymphatics** are described in Chapter 10.

The **nerves** are derived from the vaginal plexus and from the pudendal nerve.

### EXTERNAL GENITAL ORGANS

The **external genital organs** of the female (Fig. 17-64) are: (1) the **mons pubis**, (2) the **labia majora**, (3) the **labia minora**, (4) the **clitoris**, (5) the **vestibule of the vagina**, (6) the **bulb of the vestibule**, and (7) the **greater vestibular glands**. The term **pudendum** or **vulva**, as generally applied, includes all these parts.

#### *Mons Pubis*

The **mons pubis** (*mons Veneris*), the rounded eminence in front of the pubic symphysis, is formed by a collection of fatty tissue beneath the integument. It becomes covered with hair at puberty.

#### *Labia Majora*

The **labia majora** are two prominent longitudinal cutaneous folds that extend caudalward and dorsalward from the mons pubis and form the lateral boundaries of a fissure or cleft, the **pudendal cleft**, into which the vagina and urethra open. Each labium has two surfaces: an outer surface, pigmented and covered with strong, crisp hairs; and an inner surface, smooth and beset with large sebaceous follicles. Between the two is a considerable quantity of areolar tissue, fat, and a tissue resembling the dartos tunic of

**FIG. 17-64.** The female external genitalia. The labia majora and labia minora have been drawn apart.

the scrotum, besides vessels, nerves, and glands. The labia are thicker in front, where they join to form the **anterior labial commissure**. Posteriorly they are not really joined, but appear to become lost in the neighboring integument, ending close to, and nearly parallel with each other. Together with the connecting skin between them, they form the **posterior labial commissure** or posterior boundary of the pudendum. The labia majora correspond to the scrotum in the male.

### **Labia Minora**

The **labia minora** (*nymphae*) are two small folds situated between the labia majora and extending from the clitoris obliquely back-

ward for about 4 cm on either side of the orifice of the vagina; they end between the labia majora and the vaginal orifice. In the virgin, the posterior ends of the labia minora are usually joined across the midline by a fold of skin, named the **frenulum of the labia** or **fourchette**. Anteriorly, each labium minus divides into two portions: the upper division passes above the clitoris to meet its fellow of the opposite side, forming a fold that overhangs the glans clitoridis and is named the **preputium clitoridis**; the lower division passes beneath the clitoris and becomes united to its undersurface, forming, with the corresponding structure of the opposite side, the **frenulum of the clitoris**. On the opposed surfaces of the labia minora are numerous sebaceous follicles.

### **Clitoris**

The **clitoris** is an erectile structure, homologous with the penis. It is situated beneath the anterior labial commissure, partially hidden between the anterior ends of the labia minora. The **free extremity** (*glans clitoridis*) is a small rounded tubercle. It consists of two corpora cavernosa, composed of erectile tissue enclosed in a dense layer of fibrous membrane; each corpus is connected to the rami of the pubis and ischium by a crus similar to that of the penis. The clitoris, like the penis, is provided with a suspensory ligament and with two small muscles, the ischiocavernosi, which are inserted into the crura of the clitoris.

### **Vestibule**

The cleft between the labia minora and behind the glans clitoridis is named the **vestibule of the vagina**; in it are seen the urethral and vaginal orifices and the openings of the ducts of the greater vestibular glands.

The **external urethral orifice** (urinary meatus) is placed about 2.5 cm dorsal to the glans clitoridis and immediately ventral to that of the vagina; it usually assumes the form of a short, sagittal cleft with slightly raised margins.

The **vaginal orifice** is a median slit caudal and dorsal to the opening of the urethra; its size varies inversely with that of the **hymen**.

The **hymen** is a thin fold of mucous membrane situated at the orifice of the vagina; the inner edges of the fold are normally in contact with each other, and the vaginal orifice appears as a cleft between them. The hymen varies much in shape. When stretched, its commonest form is that of a ring, generally broadest posteriorly; sometimes it is represented by a semilunar fold, with its concave margin turned toward the pubes. Occasionally it is cribriform or its free margin forms a membranous fringe. It may be entirely absent or may form a complete septum across the lower end of the vagina; the latter condition is known as **imperforate hymen**. It may persist after copulation, so its presence cannot be considered a sign of virginity. When the hymen has been ruptured, small rounded elevations known as the **carunculae hymenales** are found as its

remains. Between the hymen and the frenulum of the labia is a shallow depression, named the **navicular fossa**.

### **Bulb of Vestibule**

The **bulb of the vestibule** (*vaginal bulb*) is the homologue of the bulb and adjoining part of the corpus spongiosum penis of the male. It consists of two elongated masses of erectile tissue, placed one on either side of the vaginal orifice and united to each other in front by a narrow median band termed the **pars intermedia**. Each lateral mass measures a little over 2.5 cm long. Their posterior ends are expanded and are in contact with the greater vestibular glands; their anterior ends are tapered and joined to each other by the pars intermedia; their deep surfaces are in contact with the superficial layer of the urogenital diaphragm. Superficially, they are covered by the bulbospongiosus muscle.

### **Greater Vestibular Glands**

The **greater vestibular glands** (*Bartholin's glands*) are the homologues of the bulbourethral glands in the male. They consist of two small, roundish bodies situated one on either side of the vaginal orifice in contact with the posterior end of each lateral mass of the bulb of the vestibule. Each gland opens by means of a duct, about 2 cm long, immediately lateral to the hymen, in the groove between it and the labium minus.

**VESSELS AND NERVES.** The **arteries** are derived from the internal pudendal artery through the perineal artery, the artery of the bulb, and deep and dorsal arteries of the clitoris. The **veins** drain into the pudendal plexus, which empties into the vaginal and inferior vesical veins. The **lymphatics** follow the external pudendal vessels and drain into the inguinal or external iliac nodes. The **nerves** are derived from the pudendal nerve and the pelvic plexus.

### **MAMMARY GLAND**

The mammary gland (*breast*) is an accessory of the reproductive system functionally, since it secretes milk for nourishment of the infant, but structurally and developmentally it is closely related to the integument. It reaches its typical development in

women during the early childbearing period, but is present only in a rudimentary form in infants, children, and men.

In the adult nullipara, each mamma forms a discoidal, hemispherical, or conical eminence on the anterior chest wall, extending from the second to the sixth or seventh rib, and from the lateral border of the sternum into the axilla. It protrudes 3 to 5 cm from the chest wall, and its craniocaudal diameter, approximately 10 to 12 cm, is somewhat less than its transverse diameter. Its average weight is 150 to 200 gm, increasing to 400 or 500 gm during lactation. The left mamma is generally slightly larger than the right.

The **glandular tissue** forms 15 or 20 lobes arranged radially about the nipple, each lobe having its own individual excretory duct. The glandular tissue does not occupy the entire eminence called the breast; a variable but considerable amount of adipose tissue fills out the stroma between and around the lobes. The central portion is predominantly glandular, the peripheral predominantly fat. The connective tissue stroma in many places is concentrated into fibrous bands that course vertically through the substance of the breast, attaching the deep layer of the subcutaneous fascia to the dermis of the skin. These bands are known as **suspensory ligaments of the breast** or **Cooper's ligaments**<sup>1</sup>. The entire breast is contained within the subcutaneous fascia. The deep surface is separated from the underlying external investing layer of deep fascia by a fascial cleft that allows considerable mobility. The deep surface of the breast is concave, molded over the ventral chest wall mostly in contact with the pectoral fascia, but laterally with the axillary and serratus anterior fascia, and inferiorly it may reach the obliquus externus and rectus abdominis muscles.

### Papilla

The **mammary papilla** or **nipple** projects as a small cylindrical or conical body, a little below the center of each breast at about the level of the fourth intercostal space. It is perforated at the tip by 15 or 20 minute openings, the apertures of the lactiferous ducts. The characteristic skin of the nipple, pigmented, wrinkled, and roughened by papil-

lae, extends outward on the surface of the breast for 1 or 2 cm to form the **areola**. The color of the nipple and areola in nulliparae varies from rosy pink to brown, depending on the complexion of the individual. During the second month and progressing through pregnancy, the skin becomes darker and the areola becomes larger. Following lactation the pigmentation diminishes but is never entirely lost and may be used to differentiate nulliparous from parous individuals.

### Areola

The **areola** is made rough by the presence of numerous large sebaceous glands, which produce small elevations of its surface. These **areolar glands** (glands of Montgomery<sup>2</sup>) secrete a lipoid material that lubricates and protects the nipple during nursing. The subcutaneous tissue of the areola contains circular and radiating smooth muscle bundles, which cause the nipple to become erect in response to stimulation.

### Development

The primordium of the mamma is first recognizable during the sixth week of intrauterine life as a bandlike thickening of the ectoderm of the anterolateral body wall. It extends from the axilla to the inguinal region and is called the **milk line**. The thickening of the ectoderm pushes into the subcutaneous mesoderm as it enlarges. After the eighth week, only the portion of the ridge destined to become mamma is identifiable. During the remainder of fetal life the epithelial cells proliferate, gradually forming buds and cords of cells projecting into the subcutaneous tissue, and by birth, little more than the main ducts have formed in both sexes. The glands remain in this infantile condition in the male.

**ADOLESCENT HYPERTROPHY.** The female gland changes only slightly from the infantile condition until the approach of puberty. At this time the mamma enlarges due to an increase in glandular tissue, particularly the ducts, and to a deposit of adipose tissue. The mammary papilla and areola enlarge, increase slightly in pigmentation, acquire smooth muscle, and become sensitive. After

<sup>1</sup>Sir Astley Paston Cooper (1768-1841): An English surgeon (London).

<sup>2</sup>William Fetherstone Montgomery (1797-1859): An Irish obstetrician (Dublin).

the onset of the menses, the mamma change with each period. In the premenstrual phase there is a vascular engorgement, increase in the glands, and enlargement of their lumens. During the postmenstrual phase the mamma regresses and then remains in an inactive stage until the next premenstrual phase.

**HYPERTROPHY OF PREGNANCY.** Visible enlargement of the breast begins after the second month of pregnancy and is accompanied by an increased pigmentation and enlargement of the papilla, areola, and areolar glands. The duct system develops first, reaching its completion during the first six months; the acini and secreting portion follow during the last three months. The adipose tissue is almost completely replaced by parenchyma.

The secretion from the mammary gland during the first two or three days after parturition is thin and yellowish and is called **colostrum**. The secretion of true milk begins on the third or fourth day and continues through the nursing period.

**INVOLUTION AFTER LACTATION.** At the termination of nursing, the gland gradually regresses by loss of the glandular tissue; the ducts and acini return to their former size and number, and the interstices are filled with adipose tissue. There is a slight decrease in size of the breast as a whole and it tends to become more flabby and pendulous than the nulliparous breast. The pigmentation of the nipple and the areola decreases but does not entirely disappear.

**MENOPAUSAL INVOLUTION.** At the end of the childbearing period, the mammae regress and the glandular tissue reverts toward the infantile condition. The adipose tissue disappears more slowly, especially in obese individuals, but eventually a senile atrophy occurs that leaves the mamma a shriveled pendulous fold of skin.

**HORMONAL RELATIONSHIPS.** The hypertrophy of puberty and the cyclic engorgements accompanying menstruation are responses to variations in the concentration of the ovarian sex hormones from the follicles and corpora lutea. The hypertrophy of pregnancy occurs in response to an increase in the corpus luteum hormone. The presence of the ovary is necessary only during the first part of pregnancy; later, the hormones are supplied by the placenta. Lactation is a response to the lactogenic hormone of the hypophysis, but is influenced by the nervous

system through the stimulus of suckling. Suppression of the ovarian hormones after the menopause results in the involution. Frequently the mammary glands in the newborn of both sexes secrete a fluid called "witches' milk," under the influence of the hormones passed through the placenta from the maternal circulation.

### **Structure**

The mamma consists of gland tissue, of fibrous tissue connecting its lobes, and of fatty tissue in the intervals between the lobes (Figs. 17-65; 17-66). The gland tissue, when freed from fibrous tissue and fat, is pale red, firm, flat, and thicker in the center than at the circumference.

The subcutaneous surface of the mamma has numerous irregular processes that project toward the skin and are joined to it by bands of connective tissue. It consists of numerous lobes, and these are composed of lobules, connected together by areolar tissue, blood vessels, and ducts. The smallest lobules consist of a cluster of rounded alveoli, which open into the smallest branches of the lactiferous ducts; these ducts unite to form larger ducts, and these end in a single canal, corresponding to one of the chief subdivisions of the gland. The number of excretory ducts varies from 15 to 20; they are termed the lactiferous tubules. They converge toward the areola, beneath which they form dilatations or **ampullae**, which serve as reservoirs for the milk. At the base of the papillae they become contracted and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. The ducts are composed of areolar tissue containing longitudinal and transverse elastic fibers; muscular fibers are entirely absent. The ducts are lined by columnar epithelium resting on a basement membrane.

The epithelium of the mamma differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or suckling, the alveoli are very small and solid, being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge, and the cells undergo rapid multiplication. At the commencement of lactation, the cells in the center of the alveolus undergo fatty degeneration, and are eliminated in the first milk as **colostrum corpus-**

**Fig. 17-65.** Dissection of the lateral aspect of the right mammary gland during the period of lactation.

cles. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells with spherical nuclei, lining the basement membrane. The cells during the state of activity of the gland are capable of forming oil globules in their interior, which are then ejected into the lumen of the alveolus and constitute the milk globules. When the acini are distended by the accumulation of the secretion, the lining epithelium becomes flattened.

The **fibrous tissue** invests the entire surface of the mamma. Bands of fibrous tissue traverse the gland and connect the overlying skin to the underlying deep layer of subcutaneous fascia. These constitute the ligaments of Cooper.

The **fatty tissue** covers the surface of the gland and occupies the interval between its lobes. It usually exists in considerable abundance and determines the form and size of the areola and papilla (Fig. 17-67).

FIG. 17-66. Section of portion of breast.

**VESSELS AND NERVES.** The **arteries** supplying the mammae are derived from the thoracic branches of the axillary, the intercostal, and the internal thoracic arteries. The **veins** describe an anastomotic circle around the base of the papilla, called the **circulus venosus**. From this, large branches transmit the blood to the circumference of the gland and end in the axillary and internal thoracic veins. The **lymphatics** are described in Chapter 10. The **nerves** are derived from the anterior and lateral cutaneous branches of the fourth, fifth, and sixth thoracic nerves.

**VARIATIONS.** Independent of the physiologic variations, conditions of underdeveloped breasts (*hypomastia*), hypertrophy, and inequality on the two sides are common. Variations in position, cranially or caudally, are not infrequent, as might be

FIG. 17-67. Sagittal section through lactating mammary gland. (Eycleshymer and Jones.)

expected from the method of embryologic development. Absence of the breast, *amastia*, is rare; an increase in the number of mammae, *polymastia*, is not rare. The supernumerary mammae occur somewhere along the milk line in most instances, but other locations have been reported. Not infrequently they secrete milk during normal periods of lactation. When only the nipples of the supernumerary mammae are present the condition is *polythelia*; the extra nipples occur along the milk line in the majority of cases and may be found in males, though less frequently than in females.

Racial variations may be due to genetic influences, which cause discoidal, hemispherical, pear-shaped, or conical forms to predominate. On the

other hand, various forms may be due to intentional practices such as suppressing development by tight brassières at adolescence or tremendously elongating the breasts by manipulation to make nursing convenient for an infant strapped on the back.

*Gynecomastia* is a condition in which the mammae of a male are enlarged. In pseudogynecomastia, the increase is due to adipose tissue. In the true gynecomastia, to some extent the epithelial tissue, but especially the firmer connective tissue elements are involved. A background of endocrine dysfunction is probably involved in this disorder, but this is not clearly understood.

## The Endocrine Glands

**Endocrine glands or ductless glands** are grouped together because of their common characteristics of not having ducts and of discharging their specific secretions, called hormones, into the blood stream.

**Hormones** are chemical messengers, and although they are carried by the blood to all parts of the body, only certain organs or types of cells are able to respond to their stimulation. The specific organ that does respond to a particular hormone is called its **target organ**. The body produces several hormones other than those secreted by the endocrine glands described in this chapter, such as insulin, from the islands of Langerhans<sup>1</sup> in the pancreas; androgens and estrogens, from the gonads; and secretin, from the mucous membrane of the gastrointestinal tract. The structures secreting these hormones are described in other chapters.

The endocrine glands included in this chapter are the thyroid and parathyroid glands, the hypophysis or pituitary gland,

the suprarenal glands, and the paraganglia. The pineal gland is discussed in Chapter 11, with the epithalamus. The thymus was once classified with the ductless glands but is now included in the lymphatic system.

### Thyroid Gland

#### DEVELOPMENT

The thyroid gland is developed from a median diverticulum of the ventral wall of the pharynx (Fig. 18-1) that appears about the fourth week on the summit of the tuberculum impar, but later is found in the furrow immediately caudal to the tuberculum. It grows distalward and caudalward as a tubular duct, which bifurcates and subsequently subdivides into a series of cellular cords, from which the isthmus and lateral lobes of the thyroid gland are developed. The connection of the median diverticulum with the pharynx is termed the **thyroglossal duct**; its continuity is subsequently interrupted and it degenerates, its cranial end being represented by the foramen cecum of the tongue, and its caudal end, by the pyramidal lobe of the thyroid gland.

#### ANATOMY

The thyroid gland (Fig. 18-2) is a highly vascular organ situated at the front of the neck. It consists of right and left lobes con-

**Fig. 18-1.** Scheme showing development of brachial epithelial bodies. I, II, III, IV, Branchial pouches. (Modified from Kohn.)

<sup>1</sup>Paul Langerhans (1847-1888): A German anatomist and pathologist (Berlin and Freiburg).

**Fig. 18-2.** Blood supply of the thyroid gland, viewed from in front. The thoracic duct and principal lymphatics are also shown. (Ecyleshymer and Jones.)

nected across the midline by a narrow portion, the isthmus. Its weight is somewhat variable, but usually about 30 gm. It is slightly heavier in women and becomes enlarged during pregnancy.

The **lobes** have a conical shape, the apex of each being directed cranialward and lateralward as far as the junction of the middle with the caudal third of the thyroid cartilage; the base looks caudalward and is on a level with the fifth or sixth tracheal ring. Each lobe is about 5 cm long; its greatest width is about 3 cm, and its thickness about 2 cm. The **lateral** or **superficial surface** is convex and covered by the skin, the subcutaneous and deep fasciae, the sternocleidomastoid, the superior belly of the omohyoid, the sternohyoid, and the sternothyroid. Beneath the sternothyroid muscle, the vis-

ceral layer of the deep fascia forms a capsule for the gland. The **deep** or **medial surface** is molded over the underlying structures: the trachea, the inferior pharyngeal constrictor and the posterior part of the cricothyroid muscle, the esophagus (particularly on the left side of the neck), the superior and inferior thyroid arteries, and the recurrent nerves. The **ventral border** is thin and inclines obliquely from above downward toward the midline of the neck, while the **dorsal border** is thick and overlaps the common carotid artery and, as a rule, the parathyroids.

The **isthmus** connects the lower thirds of the lobes. It measures about 1.25 cm in breadth and in depth, and usually covers the second and third rings of the trachea. Its situation and size have many variations. In the

midline of the neck it is covered by the skin and fascia, and on either side, close to the midline, by the sternothyroid. Across its cranial border runs an anastomotic branch uniting the two superior thyroid arteries; at its caudal border are the inferior thyroid veins. Sometimes the isthmus is altogether wanting.

A third conical lobe, called the **pyramidal lobe**, frequently arises from the cranial part of the isthmus or from the adjacent portions of either lobe (most commonly the left) and ascends as far as the hyoid bone. It is occasionally detached or may be divided into two or more parts.

A fibrous or muscular band is sometimes found attached to the body of the hyoid bone and to the isthmus of the gland or its pyramidal lobe. When muscular, it is termed the **levator glandulae thyroideae**.

Small detached portions of thyroid tissue are sometimes found in the vicinity of the lateral lobes or above the isthmus. They are called **accessory thyroid glands**.

### STRUCTURE

The thyroid gland is invested by a thin capsule of connective tissue, which projects into its substance and imperfectly divides it into masses of irregular form and size. When the fresh organ is cut open, its interior appears to be brownish-red and made up of closed vesicles containing colloid, which are separated from each other by intermediate connective tissue (Fig. 18-3).

The thyroid follicles (acini, vesicles) of the adult are closed sacs of inconstant shape and size. They are normally of microscopic dimensions, although macroscopically visible in colloid goiter. The follicles located peripherally may be larger than those centrally placed. The cuboidal epithelium of the normal thyroid rests directly on the delicate connective tissue surrounding the follicle. No basement membrane can be seen. The capillaries and lymphatics are thus in close contact with the secretory epithelium of the gland. The follicle normally is filled with colloid which contains the active principle of the gland, thyroxin. The thyroid epithelium may secrete this hormone directly into the colloid-filled lumen of the follicle where it is stored, or the hormone may be secreted directly into the capillaries. The stored colloid may be absorbed and liberated into the capillaries.

**FIG. 18-3.** Section of thyroid gland of a 21-year-old man. b.v., blood vessel; c., colloid; f., follicle; g.ep., glandular epithelium; s., connective tissue stroma. 120 X. (Sobotta.)

**FUNCTION.** The hormone, thyroxin, requires iodine for its elaboration, which is normally obtained in adequate amounts in the diet. Proper functioning of the thyroid gland and normal histologic structure depend upon the adequacy of available iodine. The thyroid itself is activated or regulated by another hormone, the thyrotropic hormone of the anterior pituitary gland. Removal of the thyroid results in a marked reduction of the oxidative processes of the body. This lowered metabolic rate is characteristic of hypothyroidism. In infancy and childhood, the thyroid gland is essential to normal growth of the body.

**VESSELS AND NERVES.** (Fig. 18-4). The **arteries** supplying the thyroid gland are the superior and inferior thyroid arteries and sometimes an additional branch (thyroidea ima), from the brachiocephalic artery or the arch of the aorta, which ascends upon the front of the trachea. The arteries are remarkable for their large size and frequent anastomoses. The **veins** (Fig. 18-2) form a plexus on the surface of the gland and on the front of the trachea; from this plexus the superior, middle, and inferior thyroid veins arise; the superior and middle veins end in the internal jugular vein; the inferior, in the brachiocephalic vein. The capillary blood vessels form a dense plexus in the connective tissue around the vesicles, lying between the epithelium of the vesicles and the endothelium of the lymphatics, which surround a greater or smaller part of the circumference of the vesicle. The **lymphatic vessels** run in the interlobular connective tissue, not uncommonly surrounding the arteries they accompany, and communicate with a network in the capsule of the gland; they may con-

**FIG. 18-4.** Posterior view of larynx, trachea, thyroid, and parathyroids. Relations of thyroid arteries and laryngeal nerves are shown. (Nordland, 1930.)

tain colloid material. They end in the thoracic and right lymphatic trunks. The **nerves** are derived from the middle and inferior cervical ganglia of the sympathetic system.

## Parathyroid Glands

### DEVELOPMENT

The parathyroid bodies are developed as outgrowths from the third and fourth branchial pouches (Fig. 18-1).

### ANATOMY

The **parathyroid glands** (Fig. 18-4) are small brownish-red bodies, situated as a rule between the dorsal borders of the lateral lobes of the thyroid gland and its capsule. They differ from the thyroid gland in struc-

ture, being composed of masses of cells arranged in a more or less columnar fashion with numerous intervening capillaries. They measure on an average about 6 mm long and 3 to 4 mm wide, and usually have the appearance of flattened oval discs. The parathyroid glands are divided, according to their situation, into **superior** and **inferior** glands. The superior, usually numbering two, are the more constant in position, situated, one on either side at the level of the caudal border of the cricoid cartilage, beside the junction of the pharynx and esophagus. The inferior glands, also usually two, may be applied to the caudal edge of the lateral lobes; placed at some little distance caudal to the thyroid gland; or found in relation to one of the inferior thyroid veins.

Four parathyroid glands are usually found in the human body; fewer than four were found in less than 1% of over a thousand persons (Pepere), but more than four (five or six) were found in over 33% of 122 bodies exam-

ined by Civalleri. In addition, numerous minute islands of parathyroid tissue may be found scattered in the connective tissue and fat of the neck around the parathyroid glands proper, quite distinct from them.

### STRUCTURE

Microscopically the parathyroids consist of intercommunicating columns of cells (*principal* or *chief cells*) supported by connective tissue containing a rich supply of blood capillaries (Fig. 18-5). Most of the cells are clear, but some larger cells contain oxyphil granules (*eosinophil cells*). Vesicles containing colloid have been described as occurring in the parathyroid.

**FUNCTION.** The parathyroids secrete a hormone, parathyrin or parathormone, necessary for calcium metabolism. The tetany that follows parathyroidectomy can be relieved by feeding or injecting calcium salts or parathyroid extracts.

## Hypophysis Cerebri or Pituitary Gland

### DEVELOPMENT

The hypophysis has a dual origin that corresponds to the two distinct parts of the adult gland. At an early embryonic stage, about the fourth week, when the neural tube and the primitive digestive tube are still in close proximity, outgrowths or diverticula from both tubes come in contact with each other to form the primordium of the hypophysis. The part from the neural tube is in the diencephalic floor of the hypothalamus, and is called the **infundibular process**. The part from the alimentary tube is from the portion of the future pharynx developed from ectoderm, the stomodaeum, and is known as **Rathke's pouch**.<sup>1</sup> The infundibular process retains a connection with the hypothalamus as the stalk, preserves some resemblance to neural tissue, and becomes the **neural lobe**. The cells of Rathke's pouch adhere to the infundibular process and grow

<sup>1</sup>Martin Heinrich Rathke (1793-1860): A German embryologist and anatomist (Danzig and Königsberg).

Fig. 18-5. Section of a human parathyroid gland to show principal and eosinophil cells. 250  $\times$ .

partly around it, forming the *pars tuberalis* (Fig. 18-6). The remainder of the pouch forms a double layered cup and the connection with the pharynx gradually disappears. The rostral portion of the cup thickens greatly and becomes the glandular anterior lobe or *pars distalis*. The other layer of the cup remains adherent to the neural lobe, thickens but little, and develops into the *pars intermedia*. The cavity of the original diverticulum eventually disappears except

for the vestigial lumina in the form of one or more narrow vesicles of variable length in the pars intermedia.

## ANATOMY

The **hypophysis cerebri** or **pituitary gland** is couched in the sella turcica or hypophyseal fossa of the body of the sphenoid bone. It is attached to the hypothalamus by the **stalk** or **infundibulum**. After the brain has been removed from the cranial cavity, the cut end of the stalk is visible protruding through a hole in the diaphragma sellae. The latter is a shelf of dura mater stretching between the clinoid processes and covering over the sella turcica. The two principal portions of the gland, the anterior and posterior lobes, are not easily distinguished in the whole gland, but are visible in a median sagittal section because of a difference in color.

The hypophysis is a small gland, 1.2 to 1.5 cm in its greatest diameter, which is from side to side; its rostrocaudal diameter is approximately 1 cm, and its thickness is 0.5 cm. Its weight in an adult male is 0.5 to 0.6 gm,

but varies according to the stature rather than the weight of an individual. It is larger in women, and since a slight increase occurs during pregnancy, in a multipara it may weigh as much as 1 gm.

**RELATIONS.** Many important structures lie in close proximity to the hypophysis (Fig. 18-7). The internal carotid artery emerges from the dural covering of the cavernous sinus immediately lateral to it. The intercavernous and circular sinuses are enclosed in the diaphragma sellae above it. The optic nerves, chiasma, and optic tracts lie between it and the bulk of the brain. In skulls with large sphenoid sinuses, the hypophysis may be separated from this air space only by a thin plate of bone and the dural lining of the sella. The practical importance of these relations is emphasized in patients with tumors of the hypophysis. These tumors may compress the carotid arteries or the optic nerves, causing changes in the retina known as choked discs, which are visible with the ophthalmoscope.

## LOBES

The **hypophysis** is divided into two parts on the basis of embryologic development, adult morphology, and function. The nam-

**Fig. 18-7.** A midsagittal section through the cerebrum showing the corpus callosum, anterior cerebral vessels, cerebellum, brainstem and the hypophysis cerebri located within the sella turcica.

ing of these main parts and their subdivisions results in some overlapping, which is best shown in Table 18-1 and Figure 18-8.

Anterior Lobe

The **anterior lobe** or **adenohypophysis** is larger than the posterior lobe, occupying about three-fourths of the gland. It appears darker in a sagittal section because of its vascularity and the composition of glandular tissue.

**STRUCTURE.** The **anterior lobe** or **pars distalis** is composed of cords of epithelial cells richly supplied with sinusoidal capillaries. The epithelial cells are of two main types: those that are colored by various stains, the **chromophils**, and those that remain pale or unstained, the **chromophobes**. The chromophils in turn are two kinds: those whose granules take up acid dyes, named **acidophils**, and those that take up basic dyes, the **basophils**. The basophils can again be subdivided into beta and delta types by their coloration with certain dyes. There is no definite pattern of distribution of the two chromophils, either in different parts of the gland or within individual cords. The chromophobes are smaller than the chromophils, less discrete, and tend to accumulate in the center of cords and clumps. The lack of mitotic division in the hypophysis and experimental observations indicate that the chromophils undergo cycles of secretory activity in which they discharge their specific granules and pass through a resting stage in the form of chromophobes.

Posterior Lobe

The **posterior lobe** or **neurohypophysis** has a pale color, corresponding to the overlying brain with which it is continuous by

means of the infundibulum and median eminence of the tuber cinereum.

**STRUCTURE.** The specific cell is the pituitocyte, which resembles neuroglia in shape due to its long processes. The outlines of the cells and their processes are distinguishable only in special preparations. They contain a variable number of granules and lipid globules. The inclusions, blackened by osmic acid, correspond with the neurosecretion, which is stored by them but is produced by the nerve cells of the supraoptic and paraventricular nuclei of the hypothalamus.

The **pars tuberalis** is a layer of cuboidal cells covering the stalk and neighboring area. It is richly supplied with arterial blood.

The **pars intermedia** is composed of a thin layer of epithelial cells between the neural lobe and the pars distalis. It encloses the remnants of the vestigial lumen of Rathke's pouch, which appear as vesicles containing a "colloid" resembling that of the thyroid gland in histologic preparations but having no relation to it chemically. The lining cells also may be ciliated.

**VESSELS.** The **arteries** to the hypophysis are the superior hypophyseal arteries, from the internal carotid or posterior communicating arteries, and the inferior hypophyseal arteries, which are also branches of the internal carotid but traverse the cavernous sinus. The branches of the superior arteries supply the stalk and adjacent parts of the anterior lobe (Fig. 18-9). The branches of the inferior arteries supply the posterior lobe. The blood supply of the pars distalis is mainly through a **portal system** of veins. The blood from the capillaries of the pars tuberalis and adjacent stalk collects into veins that pass along the stalk and break up into the numerous sinusoidal capillaries of the pars distalis.

The **veins** of the hypophysis are the lateral hypophyseal veins, which drain into the cavernous and intercavernous sinuses.

TABLE 18-1. Major Divisions and Subdivisions of the Mammalian Hypophysis

**Fig. 18-8.** Diagrammatic median sagittal section of the hypophysis cerebri or pituitary gland. (Atwell.)

**Fig. 18-9.** Schematic drawing of the hypophysis of the adult rhesus monkey. ar, arachnoid membrane; ba, basilar artery; bv, basilar vein; d, dura; di, sellar diaphragm; iho, inferior hypophyseal artery; lv, lateral hypophyseal veins; oc, optic chiasma; pc, posterior clinoid process; pv, portal venules; sas, subarachnoid space; sd, subdural space; sha, superior hypophyseal arteries (1, branches to hypophyseal stalk; 2, branches to anterior lobe); v, dural veins; vpi, veins of infundibular process. (Wislocki, *Pituitary Gland*, Williams & Wilkins, Baltimore, 1938.)

**NERVES.** The pars distalis has no specific innervation. Fibers from the superior cervical ganglion of the sympathetic system have been traced along the blood vessels but have not been conclusively associated with the glandular cells.

The neurohypophysis is supplied by fibers from the supraoptic and paraventricular nuclei of the hypothalamus. Similar osmiophilic neurosecretory granules are found in the cells of these nuclei and in their processes, which extend down to the posterior lobe in the **hypothalamico-hypophyseal** system in the infundibulum. Experimental evidence indicates that the hormones extracted from the neurohypophysis originate from these neurosecretions and are stored in the gland.

**FUNCTION.** The hypophysis supplies several hormones. Among those of the anterior lobe are a growth hormone, *somatotropin*, which affects general body growth; a thyrotropic hormone, which acts on the thyroid gland; an adrenocorticotrophic hormone (ACTH), which acts on the suprarenal cortex; two gonadotropic hormones, one that stimulates ovarian follicles (FSH) and another that stimulates the lutein cells (LH); and *prolactin*, which promotes milk secretion by the mammary gland. Attempts to associate the specific types of cells with the elaboration of these hormones have been partly successful. The growth hormone is produced by acidophils. Tumors of the gland composed of acidophils are found in patients with tremendous overgrowth of various parts of the body in a condition called acromegaly, and the absence of acidophils is notable in pituitary dwarfs. Acidophils also appear to be responsible for prolactin. Experimental evidence points to the basophils as the source of the follicle-stimulating, thyroid-stimulating, and luteinizing hormones. The source of adrenotropic hormone is controversial but may be a specific cell developed from chromophobes.

From the neurohypophysis, two hormones have been extracted: oxytocin (Pituitrin), which stimulates the contraction of smooth muscle and is sometimes used in obstetric practice to make the uterus contract; and the antidiuretic principle or vasopressin, which inhibits diuresis by the kidneys and also raises the blood pressure. As mentioned previously, it is doubtful that the neural lobe elaborates these hormones. A lack of the antidiuretic principle in patients produces a condition called diabetes insipidus.

## Suprarenal or Adrenal Gland

The suprarenal gland (*adrenal gland*) in man and other mammals is a combination of two distinct glands that remain independent in fishes and other more primitive vertebrates. The two organs in the human gland

are fused together but remain distinct and identifiable as the cortex and medulla of the adult gland.

### DEVELOPMENT

The **cortex** of the suprarenal gland is first recognizable in an embryo of the sixth week as a groove in the coelom at the base of the mesentery near the cranial end of the mesonephros. The cells at the bottom of the groove proliferate rapidly to form a mass in the mesenchyme extending toward the aorta. During the seventh and eighth weeks the cells become arranged into cords with dilated blood spaces between; the connection with the coelomic mesothelium is lost, and a capsule of connective tissue encloses the gland. During the remainder of fetal development the cortical tissue is composed of two zones: an outer zone of more undifferentiated cells and an inner zone of cell cords that appear to be differentiated and active in secretion. After birth the inner zone atrophies and the outer zone differentiates into the three zones of the adult gland.

The **medulla** of the suprarenal gland is developed from cells of the neural crest, which migrate ventrally along with the cells that form the sympathetic ganglia. These cells later detach themselves from the ganglia and become small knots of glandular cells scattered along the vertebral column. During the seventh and eighth weeks, a large group of the neural cells, migrating along the suprarenal vein, invades the cortex, thus establishing the primordium of the suprarenal medulla. These glandular cells of sympathetic origin contain a substance, probably the precursor of the secretion, epinephrine, which is colored brown by chromic acid. This has given them their name of **chromaffin** or **pheochrome cells**. Many of the small masses of chromaffin cells persist throughout life and are given the name **paraganglia**.

### ANATOMY

The suprarenal gland, as the name suggests, is located at the cranial pole of each of the two kidneys. They are quite different in shape on the two sides (Figs. 18-10; 18-11). The right gland resembles a pyramid, or the cocked hat of colonial days; the left is semilunar and tends to be slightly larger. The

Fig. 18-10. Supracrenal glands, ventral view.

length and width vary from 3 to 5 cm and the thickness 4 to 6 mm. The average weight is 3.5 to 5 gm.

**RELATIONS.** The **right suprarenal** is situated dorsal to the inferior vena cava and right lobe of the liver, and ventral to the diaphragm and cranial end of the right kidney. The *ventral surface* has two areas: a medial, narrow, and nonperitoneal surface, which lies cranial to the inferior vena cava; and a lateral, somewhat triangular, surface in contact with the liver. The cranial part of the latter surface is devoid of peritoneum, and is in relation with the bare area of the liver near its caudal and medial angle, while its caudal portion is covered by peritoneum, reflected onto it from the inferior layer of the coronary ligament; occasionally the duodenum overlaps the inferior portion. A little below the apex and near the ventral border of the gland is a short furrow termed the **hilum**, from which the suprarenal vein emerges to join the inferior vena cava. The *posterior surface* is divided into cranial and caudal parts by a curved ridge: the cranial, slightly convex, rests upon the diaphragm; the caudal, concave, is in contact with the cranial end and the adjacent part of the ventral surface of the kidney.

The **left suprarenal** has a crescentic shape, its

concavity being adapted to the medial border of the cranial part of the left kidney. Its *ventral surface* has two areas: a cranial one, covered by the peritoneum of the omental bursa, which separates it from the cardiac end of the stomach and sometimes from the cranial extremity of the spleen; and a caudal one, which is in contact with the pancreas and splenic artery and therefore is not covered by the peritoneum. On the ventral surface, near its caudal end, is a furrow or **hilum**, from which the suprarenal vein emerges. Its *posterior surface* has a vertical ridge, which divides it into two areas; the lateral area rests on the kidney, and the medial and smaller area rests on the left crus of the diaphragm.

The surface of the suprarenal gland is surrounded by areolar tissue containing much fat. It is closely invested by a thin fibrous capsule, which is difficult to remove because of the numerous fibrous processes and vessels entering the organ through the furrows on its ventral surface and base.

#### ACCESSORY GLANDS

**Accessory suprarenals** occur frequently in the connective tissue near the main gland, but they may occur near the testis or the

Fig. 18-11. Supracrenal glands, dorsal view.

ovary, where small groups of embryonic cells might have migrated with the mesonephros, especially in certain hermaphroditic conditions. They are usually small round bodies composed of cortical cells. Larger ones may have the cortical zones represented and rarely contain central medullary tissue.

### STRUCTURE

The suprarenal gland consists of two portions, an outer **cortex** that takes up the greater part of the organ and an inner **medulla** (Fig. 18-12). In the fresh condition the outer cortex is a deep yellow, the inner part a dark red or brown, and the medulla a pale pink. At the transition between the cortex and medulla, there is no connective tissue barrier, and the cords of the two types of cells are intermingled for a short distance.

The **cortical portion** consists of a fine connective-tissue network, in which is embedded the glandular epithelium. The epithelial cells are polyhedral and possess rounded nuclei; many of the cells contain coarse granules, and others have lipoid globules. Owing to differences in the arrangement of the cells, three distinct zones can be made out: (1) The **zona glomerulosa**, situated beneath the capsule, consists of cells arranged in rounded groups, with indications here and there of an alveolar structure; the cells of this zone are highly granular and stain

deeply. (2) The **zona fasciculata**, continuous with the zona glomerulosa, is composed of columns of cells arranged in a radial manner; these cells contain finer granules and in many instances globules of lipoid material. (3) The **zona reticularis**, in contact with the medulla, consists of cylindrical masses of cells irregularly arranged; these cells often contain pigment granules, which give this zone a darker appearance than the rest of the cortex (Fig. 18-13).

The **medullary portion** is highly vascular and consists of large chromaffin cells arranged in a network. The irregular polyhedral cells have a finely granular cytoplasm that is probably concerned with the secretion of epinephrine. In the meshes of the cellular network are large anastomosing venous sinuses (sinusoids), which are in close relationship with the chromaffin or medullary cells. In many places the endothelial lining of the blood sinuses is in direct contact with the medullary cells. Some authors believe the endothelium is absent in places and here the medullary cells are directly bathed by the blood. This intimate relationship between the chromaffin cells and the blood stream undoubtedly facilitates the discharge of the internal secretion into the blood. There is a loose meshwork of supporting connective tissue containing nonstriated muscle fibers. This portion of the gland is richly supplied with nonmedullated nerve fibers, and here and there sympathetic ganglia are found.

**VESSELS AND NERVES.** The suprarenals are highly vascular organs. The arteries are numerous and comparatively large. These arteries are derived from the aorta and the inferior phrenic and the renal arteries. Three sets of branches penetrate the capsule, one of which breaks up in capillaries that supply the capsule. The second set breaks up into capillaries that supply the cell cords of the cortex and empty into veins in the medulla. The third set of arteries traverses the cortex to supply the medulla only and breaks up into the sinusoids of the medulla. Venous blood from the capsule is collected into veins of the capsule. Blood from the two other sets of arteries is gathered into the central vein in the medulla, which emerges at the hilum as the suprarenal vein. On the right side this vein opens into the inferior vena cava; on the left, into the left renal vein.

Lymphatics accompany the large blood vessels and end in the lumbar nodes.

The **nerves** are numerous and are derived from the celiac and renal plexuses. They enter the lower and medial part of the capsule, traverse the cortex, and end around the cells of the medulla. They have numerous small ganglia in the medullary portion of the gland.

**FUNCTION.** The adrenal medulla elaborates an internal secretion, epinephrine (Adrenalin), which has definite sympathomimetic actions such as causing constriction of arterioles, acceleration of the heart rate, and contraction of the radial muscle of the iris. In man an injection of the drug epinephrine

hydrochloride increases systolic blood pressure, pulse rate, minute volume of the heart, and volume of respiration. These effects are transitory and disappear after one or two hours. A rise in blood sugar and basal metabolic rate follows injection of this drug due to an increased enzymatic breakdown of glycogen in liver and muscle. The duration of epinephrine action is brief, the hormone being rapidly inactivated in the body.

The adrenal cortex elaborates one or more hormones essential to maintenance of life. Various fractions serve in the maintenance of physiologic "steady states," the regulation of the distribution of water and electrolytes, and many aspects of carbohydrate metabolism and muscular efficiency.

## Paraganglia, Glomera, and "Glands" or "Bodies"

The various structures that have been given these names are for the most part small, difficult to demonstrate, and frequently misnamed. The following is an attempt to sort them out and give their appropriate names and synonyms.

### PARAGANGLIA

The **paraganglia** (*chromaffin bodies*; *pheochrome bodies*) are small groups of chromaffin cells connected with the ganglia of the sympathetic trunk and the ganglia of the celiac, renal, suprarenal, aortic, and hypogastric plexuses. They are sometimes found in connection with the ganglia of other sympathetic plexuses.

### AORTIC BODIES OR LUMBAR PARAGANGLIA

The **aortic glands** or **bodies** (*corpora para-aortica*, *glands or organs of Zuckerkandl*<sup>1</sup>) are the largest of these groups of chromaffin cells, about 1 cm long in the newborn. They lie one on either side of the aorta in the region of the inferior mesenteric artery. They decrease in size with age and after puberty are only visible with the microscope. Other groups of chromaffin cells have been found associated with the sympathetic plexuses of the abdomen independently of the ganglia.

<sup>1</sup>Emil Zuckerkandl (1849-1910): An Austrian anatomist (Graz and Vienna).

**GLOMUS COCCYGEUM**

The **glomus coccygeum** (coccygeal gland or body; *Luschka's gland*<sup>2</sup>) is placed ventral to, or immediately distal to, the tip of the coccyx. It is about 2.5 mm in diameter and is irregularly oval in shape; several smaller nodules are found around or near the main mass.

It consists of irregular masses of round or polyhedral cells, with each mass grouped

<sup>2</sup>Hubert von L. Luschka (1820-1875): A German anatomist (Tübingen).

around a dilated sinusoidal capillary vessel. Each cell contains a large round or oval nucleus, the protoplasm surrounding which is clear and not stained by chromic salts. It is not a chromaffin paraganglion, and since its structure is not like that of the chemoreceptors (carotid bodies), its function is unknown.

The **glomus caroticum** or carotid body is not a paraganglion but a chemoreceptor.

The **glomus aorticum** is better named the **cardioaortic body** or **glomus aorticum supracardiale**. It is a chemoreceptor similar to the carotid body.

# Index

**Boldface numerals indicate a figure; numerals followed by a t indicate a table.**

A band(s), 593-594, **595**, **596**, **597**  
 Abdomen, 1448-1450, **1450**, **1451**, **1452**  
   apertures of, 1449  
   arteries of, 728-748  
   boundaries of, 1448-1449  
   disposition of viscera in, 1449-1450, **1450**, **1451**, **1452**  
   lymphatic vessels and nodes of, **892**, 896-912, **909**, **910**  
   muscles and fasciae of, 483-498  
     development of, 430  
   planes of, 88, **91**  
   quadrants of, 88  
   regions of, 88, **91**  
   surface and topographical anatomy of, 85-96, **86**, **87**, **89**, **90**, **92**, **93**, **94**, **95**  
   veins of, 834-839  
   visceral afferent fibers from, 1246-1247  
 Abdominal aorta, 731-733, **732**  
   position of, 1450, **1452**  
   surface projection of, 95-96, **95**, **97**  
 Abdominal aortic plexus, **1252**, **1266**, **1267**, 1271  
 Abdominal inguinal ring, 88, **97**, **496**, 497  
 Abducent nerve (VI), **1150**, 1152t, **1157**, 1170, **1170**, **1183**  
   development of, 944, 957  
 Abduction, 3, 4, 336  
 Abductor digiti minimi, of foot, **585**, 586-587  
   of hand, **551**, 552-553, **553**  
 Abductor hallucis, **585**, 586  
 Abductor indicis, 554  
 Abductor ossis metatarsi quinti, 587  
 Abductor pollicis brevis, 550, **551**, **553**

Abductor pollicis longus, **530**, **534**, 539-540, **539**  
 Abscess(es) of hands, spread of, 549-550  
 Accelerator urinae, **503**, 508, **509**  
 Accessory basal amygdaloid nucleus, 1055  
 Accessory cephalic vein, 822, **822**  
 Accessory cystic artery, 738  
 Accessory hemiazygos vein, 828  
   development of, 791  
 Accessory left gastric artery, 734  
 Accessory meningeal artery, 680  
 Accessory nerve (XI), **1150**, 1153t, **1181**, **1182**, **1183**, 1189, **1200**  
   development of, 956, **956**, 957  
   roots of, 963, **978**, 979  
   surface markings for, 78, 79, **80**  
 Accessory obturator nerve, **1226**, 1231  
 Accessory olivary nucleus, dorsal, **943**, 979  
   medial, **943**, 979  
 Accessory phrenic nerve, 1207  
 Accessory process(es), 137, **138**  
 Accessory pudendal artery, 756  
 Accessory renal artery(-ies), 746  
 Accessory saphenous vein, 846, **846**  
 Accessory sinus(es) of nose. See *Paranasal sinus(es)*  
 Accessory vertebral vein, 820  
 Accompanying vein of hypoglossal nerve, 818-819, **819**  
 Acetabular branch of medial femoral circumflex artery, 767  
 Acetabular branch of obturator artery, 753  
 Acetabular fossa, **266**, 269  
 Acetabular labrum, 393-394, **394**  
 Acetabular ligament, transverse, 393, **393**, 394, **394**  
 Acetabular notch, **264**, **266**, 269  
 Acetabulum, **264**, **266**, 269  
   lunate surface of, 262, **266**, 267, 269  
   sex differences in, 273, 274  
 Acetylcholine, 436  
 Acetylcholine receptor(s), 436  
 Achilles' tendon, 110, **111**, **112**, 576, 577, **582**  
 Acid mucopolysaccharides, in ground substance, 308  
 Acidophil(s), 1602  
 Acidophylus, external, 73, 160-161, **160**, 201, 1317-1319, **1318**  
   development of, 1313  
   internal, **171**, 173, **195**, 199  
 Acoustic nerve. See *Vestibulocochlear nerve*  
 Acrocentric chromosome, 15, **16**  
 Acromegaly, 1604  
 Acromial angle, 231, **231**  
 Acromial branch of suprascapular artery, 704  
 Acromial branch of thoracoacromial artery, **695**, 712, **714**  
 Acromial bursa, subcutaneous, 374  
 Acromial rete, 712  
 Acromioclavicular joint, 103, 368-370, **368**, **369**, **372**

Acromioclavicular ligament, 369, **369**  
 Acromion, **81**, **87**, 99, **101**, 230-231, **230**, **231**  
 Acrosomal cap, 21, **22**, 23, **23**  
 Acrosomal vesicle, 21-23  
 Acrosome, 21, 23  
 Actin myofilament(s), 594-595, **596**, **597**  
 Actomyosin complex, 595  
 Adamkiewicz, artery of, 969  
 Adam's apple, 74, **76**, 1366, **1374**  
 Adduction, 3, 4, 336  
 Adductor brevis, **108**, 564, **565**  
 Adductor canal, **109**, 110, 763  
 Adductor hallucis, **588**, 589  
 Adductor longus, **108**, **109**, **561**, 564, **565**  
 Adductor magnus, **108**, **109**, **561**, 565, **565**  
 Adductor minimus, 565  
 Adductor pollicis, 551-552, **551**, **552**, **553**  
 Adductor tubercle, 107, **278**, 279, 280  
 Adductor-interosseous compartment, 547-548, **547**  
 Adenohypophysis, 1602, 1602t, **1603**

 Anterior basal vein, 796-797  
 Anterior bronchial branch(es) of vagus nerve, 1187-1188  
 Anterior canaliculus of chorda tympani, 197  
 Anterior cardiac vein(s), 799  
 Anterior cardinal vein(s), 788-790, **789**, **791**, **792**, **794**  
 Anterior cecal branch of ileocolic artery, 742, **742**  
 Anterior cerebral artery, 688-690, **689**, **690**, **692**, **693**, **1110**, **1116**, 1119-1121, **1119**, **1121**  
 development of, **1111**  
 Anterior cerebral vein, 807  
 Anterior cervical cutaneous nerve, **80**, 1201-1202, **1201**  
 Anterior cervical intertransverse muscle(s), 473  
 Anterior cervical lymph node(s), 886  
 Anterior chamber, **1291**, 1294, **1300**  
 development of, 1290  
 Anterior choroidal artery, 692-693, **1110**, **1111**, 1114  
 Anterior ciliary artery(-ies), 688  
 Anterior clinoid process, **171**, 172, **203**, **204**, 206  
 Anterior commissure, **1052**, **1057**, **1059**, 1060-1061  
 development of, 953, **954**  
 Anterior communicating artery, **689**, 690, **693**, **1110**, **1119**, 1120  
 Anterior coronary plexus, **1252**, 1270  
 Anterior corticospinal tract, 979  
 Anterior cranial fossa, 170-171, **171**  
 fractures of, 179  
 Anterior cruciate ligament of knee, **400**, 401, **401**, **402**, **403**, **404**  
 Anterior crural intermuscular septum, 573  
 Anterior crural nerve. See *Femoral nerve*  
 Anterior cuneolingual gyrus, 1047  
 Anterior cutaneous cervical nerve, **80**, 1201-1202, **1201**  
 Anterior cutaneous nerve(s) of thorax, 1223, **1223**  
 Anterior deep temporal nerve, 1167  
 Anterior diaphragmatic lymph node(s), 894

- Anterior dorsal nucleus, 1019, 1021  
 Anterior epiploic artery(-ies), 734  
 Anterior ethmoidal artery, 686, 687  
 Anterior ethmoidal branch(es) of nasociliary nerve, 1161  
 Anterior ethmoidal canal, 194, 209, 209  
 Anterior ethmoidal foramen, 165, 166, 170, 171  
 Anterior ethmoidal nerve, 1157, 1158, 1161  
 Anterior external arcuate fiber(s), 976, 979  
 Anterior external vertebral venous plexus(es), 830, 830, 831  
 Anterior fontanelle, 71, 177, 177, 178  
 Anterior funiculus (ventral f.), 963, 963  
   development of, 937, 937  
 Anterior gluteal line, 263, 264, 266  
 Anterior horizontal ramus of lateral sulcus, 1037, 1037, 1038  
 Anterior horn of lateral ventricle, 1103, 1104, 1105, 1105, 1107  
 Anterior humeral circumflex artery, 712, 713, 714-715, 714  
 Anterior hypothalamic nucleus, 1031, 1032  
 Anterior ileocolic lymph node(s), 912  
 Anterior inferior cerebellar artery, 689, 693, 700-701, 700, 1007, 1008, 1010  
 Anterior inferior iliac spine, 264, 265-267, 266  
 Anterior inferior pancreaticoduodenal vein, 839  
 Anterior intercavernous sinus, 812, 813  
 Anterior intercondylar area of tibia, 284, 286  
 Anterior intercostal artery(-ies), 85, 707, 708  
 Anterior intercostal vein(s), 85, 826  
 Anterior internal vertebral venous plexus(es), 830, 830, 831  
 Anterior interosseous artery, 721, 722, 725  
 Anterior interosseous cleft, 529-530  
 Anterior interosseous ligament of tarsus, 413, 414  
 Anterior interosseous nerve, 1215  
 Anterior interventricular sulcus, 625, 627  
 Anterior jugular communicating vein, 87  
 Anterior jugular vein, 817, 817  
 Anterior labial commissure, 1580, 1580  
 Anterior lacrimal crest, 216  
 Anterior lateral malleolar artery, 774-775, 776  
 Anterior lateral sulcus, 976-977  
 Anterior ligament of auricula, 1317  
 Anterior ligament of head of fibula, 408  
 Anterior ligament of malleus, 1320, 1326  
 Anterior ligament of uterus, 1576  
 Anterior longitudinal ligament, 341, 344, 346, 347, 350  
 Anterior malleolar fold, 1321, 1321  
 Anterior medial malleolar artery, 774, 774  
 Anterior medial nucleus, 1019, 1021  
 Anterior median fissure, of medulla oblongata, 976, 978  
   of spinal cord, 961-962, 961, 962, 963  
 Anterior median longitudinal artery of spinal cord. See Anterior spinal artery  
 Anterior median spinal vein, 832, 972, 974, 975  
 Anterior mediastinal lymph node(s), 892, 894  
 Anterior medullary artery, great, 969  
 Anterior medullary feeder artery (-ies), 966, 969-970  
 Anterior medullary vein(s), 973, 974-975  
   great, 975  
 Anterior meningeal branch of internal carotid artery, 685  
 Anterior meniscofemoral ligament, 403  
 Anterior middle cerebral artery, 1120  
 Anterior nasal spine, 162, 214, 215, 218  
 Anterior neuropore, 36, 39  
 Anterior oblique carpometacarpal ligament of thumb, 387  
 Anterior obturator tubercle, 270  
 Anterior olfactory nucleus, 1051, 1052  
 Anterior orbital gyrus, 1048, 1048  
 Anterior palatine nerve, 1164, 1168  
 Anterior papillary muscle, of left ventricle, 631, 634  
   of right ventricle, 629, 633  
 Anterior paraventricular nucleus of thalamus, 1021  
 Anterior parietal artery, 1115, 1118, 1118  
 Anterior parolfactory sulcus, 1046, 1046  
 Anterior perforated substance, 1053, 1053  
 Anterior position, 2, 3  
 Anterior pulmonary branch(es) of vagus nerve, 1187-1188  
 Anterior pulmonary plexus, 1188, 1204  
 Anterior radicular vein(s), 972, 976  
 Anterior recess of Trötsch, 1327  
 Anterior root(s). See Ventral root(s)  
 Anterior segmental artery, of left lung, 660, 661  
   of right lung, 659, 660  
 Anterior segmental vein(s), 795, 796  
 Anterior semicircular canal, 1328, 1329-1330, 1329, 1330  
 Anterior semicircular duct, 1332-1334, 1332, 1333  
 Anterior spinal artery, 689, 693, 699, 699, 700, 964-967, 965, 966  
   intramedullary branches from, 970-971  
 Anterior spinocerebellar tract, 979  
 Anterior sternoclavicular ligament, 366-367, 367  
 Anterior superior alveolar branch(es) of infraorbital artery, 679, 681  
 Anterior superior alveolar branch of maxillary nerve, 1162, 1165  
 Anterior superior dental branch of maxillary nerve, 1162, 1165  
 Anterior superior iliac spine, 87, 88, 107, 107, 264, 264, 265, 266  
 Anterior superior pancreaticoduodenal vein, 838-839, 838  
 Anterior supraclavicular nerve(s), 1201, 1202  
 Anterior talocalcaneal ligament, 413, 414  
 Anterior talofibular ligament, 410, 410, 411  
 Anterior temporal artery, 691, 1114, 1115, 1116, 1117  
 Anterior temporal branch of lateral occipital artery, 1113, 1116  
 Anterior temporal branch of posterior cerebral artery, 690, 702  
 Anterior temporal diploic vein, 814, 814  
 Anterior thalamic radiation, 1099  
 Anterior thalamic tubercle, 1018, 1019  
 Anterior tibial artery, 111, 112, 771, 773, 774, 776, 778  
 Anterior tibial lymph node, 915-916  
 Anterior tibial lymphatic vessel(s), 915  
 Anterior tibial nerve, 1229, 1230, 1231, 1241-1243, 1242  
 Anterior tibial recurrent artery, 772, 774, 774, 776  
 Anterior tibial vein(s), 849  
 Anterior tibiofibular ligament, 409, 410, 411  
 Anterior tibiotalar part of deltoid ligament, 410  
 Anterior triangle, of neck, 75-78, 77, 461  
   of perineum, 96, 502  
 Anterior tympanic artery, 678, 679  
 Anterior ulnar recurrent artery, 718, 720, 725  
 Anterior vagus nerve, 1185-1186, 1188, 1266, 1267  
   branches of, 1188-1189  
 Anterior ventral nucleus, 1019-1021  
 Anterior vertebral vein, 820, 821  
 Anterior vesical lymph node(s), 903  
 Anterior white column. See Anterior funiculus  
 Anterolateral central artery(-ies). See Lenticulostriate artery (-ies)  
 Anterolateral spinal vein(s), 832, 973, 974  
 Anterolateral sulcus, 961, 963, 963
